Preface

Current Medical Diagnosis & Treatment 2010 is the 49th annual volume of this single-source reference for practitioners in both hospital and ambulatory settings. Annually updated, this book emphasizes the practical features of clinical diagnosis and patient management in all fields of internal medicine and in specialties of interest to primary care practitioners and to subspecialists who provide general care.

Intended Audience

House officers, medical students, and all other health professions students will find the descriptions of diagnostic and therapeutic modalities, with citations to the current literature, of everyday usefulness in patient care.

Internists, family physicians, hospitalists, nurse practitioners, physicians' assistants, and all primary care providers will appreciate *CMDT* as a ready reference and refresher text. Physicians in other specialties, pharmacists, and dentists will find the book a useful basic medical reference text. Nurses, nurse-practitioners, and physicians' assistants will welcome the format and scope of the book as a means of referencing medical diagnosis and treatment.

Patients and their family members who seek information about the nature of specific diseases and their diagnoses and treatment may also find this book to be a valuable resource.

New in this Edition

- Newly introduced topics include H1N1 influenza A (swine flu), Chikungunya fever, acute knee pain, neuromyelitis optica, and vaccine safety
- Cancer chapter totally rewritten by new authors
- Substantially updated Treatment sections for HIV infection & AIDS, female breast cancer, Kawasaki disease, and pneumocystosis
- New recommendations for use of nonsteroidal anti-inflammatory agents, coxib agents, and antiplatelet agents in patients with peptic ulcer disease
- Significant revision of antithrombotic therapy
- New recommendations for intervention in patients with patent ductus arteriosus
- New ACC/AHA Task Force Guidelines for management of congenital heart disease in pregnant women
- Reorganization of obstetric complications by trimester
- Extensive revision of hypokalemia, hyperkalemia, hypophosphatemia, and mixed acid-base disorders;

sexually transmitted diseases; penicillin-resistant pneumococcus; ionizing radiation exposure
- Drug information, bibliographies, and Web sites updated through June 2009
- Expanded 24-page color insert

Outstanding Features

- Medical advances up to time of annual publication
- Detailed presentation of all primary care topics, including gynecology, obstetrics, dermatology, ophthalmology, otolaryngology, psychiatry, neurology, toxicology, urology, geriatrics, preventive medicine, and palliative care
- Concise format, facilitating efficient use in any practice setting
- More than 1000 diseases and disorders
- Only text with annual update on HIV infection
- Specific disease prevention information
- Easy access to drug dosages, with trade names indexed and costs updated in each edition
- Recent references, with unique identifiers (PubMed, PMID numbers) for rapid downloading of article abstracts and, in some instances, full-text reference articles
- ICD-9 codes listed on the inside covers

CMDT Online (www.AccessMedicine.com) provides full electronic access to CMDT 2010 plus expanded basic science information. CMDT Online is updated quarterly and includes a dedicated Media Gallery as well as links to related Web sites. Subscribers also receive access to Diagnosaurus with 1000+ differential diagnoses and *CURRENT Practice Guidelines in Primary Care, 2008*.

The four online-only chapters (Anti-infective Chemotherapeutic & Antibiotic Agents, Diagnostic Testing & Medical Decision Making, Basic Genetics, and Information Technology in Patient Care) are available at www.AccessMedicine.com/CMDT.

Acknowledgements

We wish to thank our associate authors for participating once again in the annual updating of this important book. We are especially grateful to seven authors who are leaving *CMDT* this year: Joshua S. Adler, MD; Catherine K. Chang, MD; Masafumi Fukagawa, MD, PhD; Christopher J. Kane, MD, FACS; Kiyoshi Kurokawa, MD, MACP; James A. Murray, DO; and Hope S. Rugo, MD. These authors have contributed hours upon hours of work in culling and distilling the literature in their specialty areas and we have all benefited from their clinical wisdom and commitment.

Many students and physicians also have contributed useful suggestions to this and previous editions, and we are grateful. We continue to welcome comments and recommendations for future editions in writing or via electronic mail. The editors' and authors' institutional and e-mail addresses are given in the Authors section.

1

General Approach to the Patient

The medical interview serves several functions. It is used to collect information to assist in diagnosis (the "history" of the present illness), to assess and communicate prognosis, to establish a therapeutic relationship, and to reach agreement with the patient about further diagnostic procedures and therapeutic options. It also serves as an opportunity to influence patient behavior, such as in motivational discussions about smoking cessation or medication adherence. Interviewing techniques that avoid domination by the clinician increase patient involvement in care and patient satisfaction. Effective clinician-patient communication and increased patient involvement can improve health outcomes.

Patient Adherence

For many illnesses, treatment depends on difficult fundamental behavioral changes, including alterations in diet, taking up exercise, giving up smoking, cutting down drinking, and adhering to medication regimens that are often complex. Adherence is a problem in every practice; up to 50% of patients fail to achieve full compliance, and one-third never take their medicines. Many patients with medical problems, even those with access to care, do not seek appropriate care or may drop out of care prematurely. Adherence rates for short-term, self-administered therapies are higher than for long-term therapies and are inversely correlated with the number of interventions, their complexity and cost, and the patient's perception of overmedication.

As an example, in HIV-infected patients, adherence to antiretroviral therapy is a crucial determinant of treatment success. Studies have unequivocally demonstrated a close relationship between patient adherence and plasma HIV RNA levels, CD4 cell counts, and mortality. Adherence levels of > 95% are needed to maintain virologic suppression. However, studies show that over 60% of patients are < 90% adherent and that adherence tends to decrease over time.

Patient reasons for nonadherence include simple forgetfulness, being away from home, being busy, and changes in daily routine. Other reasons include psychiatric disorders (depression or substance abuse), uncertainty about the effectiveness of treatment, lack of knowledge about the consequences of poor adherence, regimen complexity, and treatment side effects.

Patients seem better able to take prescribed medications than to comply with recommendations to change their diet, exercise habits, or alcohol intake or to perform various self-care activities (such as monitoring blood glucose levels at home). The effectiveness of interventions to improve medication adherence has been reviewed by Haynes and colleagues. For short-term regimens, adherence to medications can be improved by giving clear instructions. Writing out advice to patients, including changes in medication, may be helpful. Because low functional health literacy is common (almost half of English-speaking US patients are unable to read and understand standard health education materials), other forms of communication—such as illustrated simple text, videotapes, or oral instructions—may be more effective. For non–English-speaking patients, clinicians and health care delivery systems can work to provide culturally and linguistically appropriate health services.

To help improve adherence to long-term regimens, clinicians can work with patients to reach agreement on the goals for therapy, provide information about the regimen, ensure understanding by using the "teach-back" method, counsel about the importance of adherence and how to organize medication-taking, reinforce self-monitoring, provide more convenient care, prescribe a simple dosage regimen for all medications (preferably one or two doses daily), suggest ways to help in remembering to take doses (time of day, mealtime, alarms) and to keep appointments, and provide ways to simplify dosing (medication boxes). Single-unit doses supplied in foil-backed wrappers can increase adherence but should be avoided for patients who have difficulty opening them.

Medication boxes with compartments (eg, Medisets) that are filled weekly are useful. Microelectronic devices can provide feedback to show patients whether they have taken doses as scheduled or to notify patients within a day if doses are skipped. Reminders are another effective means of encouraging adherence. The clinician can also enlist social support from family and friends, recruit an adherence monitor, provide a more convenient care environment, and provide rewards and recognition for the patient's efforts to follow the regimen.

Adherence is also improved when a trusting doctor-patient relationship has been established and when patients actively participate in their care. Clinicians can improve patient adherence by inquiring specifically about the behaviors in question. When asked, many patients admit to incomplete adherence with medication regimens, with advice about giving up cigarettes, or with engaging only in "safer sex" practices. Although difficult, sufficient time must be made available for communication of health messages.

Medication adherence can be assessed generally with a single question: "In the past month, how often did you take your medications as the doctor prescribed?" Other ways of assessing medication adherence include pill counts and refill records; monitoring serum, urine, or saliva levels of drugs or metabolites; watching for appointment nonattendance and treatment nonresponse; and assessing predictable drug effects such as weight changes with diuretics or bradycardia from -blockers. In some conditions, even partial adherence, as with drug treatment of hypertension and diabetes mellitus, improves outcomes compared with nonadherence; in other cases, such as HIV antiretroviral therapy or treatment of tuberculosis, partial adherence may be worse than complete nonadherence.

Guiding Principles of Care

Ethical decisions are often called for in medical practice, at both the "micro" level of the individual patient-clinician relationship and at the "macro" level of the allocation of resources. Ethical principles that guide the successful approach to diagnosis and treatment are honesty, beneficence, justice, avoidance of conflict of interest, and the pledge to do no harm. Increasingly, Western medicine involves patients in important decisions about medical care, including how far to proceed with treatment of patients who have terminal illnesses (see Chapter 5: Palliative Care & Pain Management).

The clinician's role does not end with diagnosis and treatment. The importance of the empathic clinician in helping patients and their families bear the burden of serious illness and death cannot be overemphasized. "To cure sometimes, to relieve often, and to comfort always" is a French saying as apt today as it was five centuries ago—as is Francis Peabody's admonition: "The secret of the care of the patient is in caring for the patient."

Denberg TD. Effect of a mailed brochure on appointment-keeping for screening colonoscopy: a randomized trial. Ann Intern Med. 2006 Dec 19;145(12):895–900. [PMID: 17179058]

Kripalani S. Interventions to enhance medication adherence in chronic medical conditions: a systematic review. Arch Intern Med. 2007 Mar 26;167(6):540–50. [PMID: 17389285]

Health Maintenance & Disease Prevention

Preventive medicine can be categorized as primary, secondary, or tertiary. Primary prevention aims to remove or reduce disease risk factors (eg, immunization, giving up or not starting smoking). Secondary prevention techniques promote early detection of disease or precursor states (eg, routine cervical Papanicolaou screening to detect carcinoma or dysplasia of the cervix). Tertiary prevention measures are aimed at limiting the impact of established disease (eg, partial mastectomy and radiation therapy to remove and control localized breast cancer). Table 1–1 gives data for deaths from preventable causes in the United States. Table 1–2 compares recommendations for periodic health examinations as developed by the United States Preventive Services Task Force, the American College of Physicians, and the Canadian Task Force on the Periodic Health Examination. Despite emerging consensus on many of the services, controversy persists for others. Many effective preventive services are underutilized, and few adults receive all of the most strongly recommended services. In 2006, the National Commission on Prevention Priorities ranked clinical preventive service recommendations up to December 2004. The three highest-ranking services were discussing aspirin use with high-risk adults, tobacco-use screening and brief interventions, and immunizing children. Other high-ranking services with data indicating low current utilization rates (< 50%) included screening adults aged 50 and older for colorectal cancer, immunizing adults aged 65 and older against pneumococcal disease, and screening young women for *Chlamydia*. Several methods, including the use of reminder systems or financial incentives, can increase utilization of preventive services, but such methods have not been widely adopted.

Table 1–1. Estimated annual deaths from preventable causes in the United States in 2000.

Preventable Cause	**Estimated Number of Deaths (% total deaths)**
Tobacco	435,000 (18%)
Poor diet and physical inactivity	365,000 (15%)
Alcohol	85,000 (3%)
Motor vehicle	43,000 (2%)
Firearms	29,000 (1%)
Illicit drug use	17,000 (0.7%)

Table 1–2. Expert recommendations for preventive care

for asymptomatic, low-risk adults.

Preventive Service	**USPSTF[1]**	**CTF[2]**	**Other Organizations**
Screening tests			
Blood pressure	Recommended for all adults; interval not stated	Fair evidence for inclusion in routine care	Joint National Committee VII: Recommended for all adults at each clinical encounter
Serum lipids	Recommended for all middle-aged and older adults and for young adults with multiple risk factors	Insufficient evidence for or against inclusion	National Cholesterol Education Panel Adult Treatment Panel III: Recommended for all adults age 21 and older
Depression	Recommended	Recommen	

screening	when support systems in place (B recommendation)	ded when support systems in place	
Counseling			
Healthy diet	Recommended for patients with increased risk; insufficient evidence for or against in average-risk patients	Fair evidence for inclusion	
Physical activity	Recommended	Fair evidence for inclusion	
Immunizations and chemoprevention			
Aspirin chemoprevention	Recommended for adults at increased risk for coronary heart disease (CHD)	Insufficient evidence for or against use	American Heart Association: Recommended for adults at increased risk for

			CHD
Influenza vaccination	Recommended for all adults 65 and older and for selected high-risk groups	Not addressed	
Pneumococcal vaccination	Recommended for immunocompetent adults older than age 65 or for adults younger than age 65 at increased risk	Recommended for healthy adults

Prevention of Infectious Diseases

Much of the decline in the incidence and fatality rates of infectious diseases is attributable to public health measures—especially immunization, improved sanitation, and better nutrition.

Low N et al. Global control of sexually transmitted infections. Lancet. 2006 Dec 2;368(9551):2001–16. [PMID: 17141708]

Immunization remains the best means of preventing many infectious diseases. In the United States, childhood immunization has resulted in near elimination of measles, mumps, rubella, poliomyelitis, diphtheria, pertussis, and tetanus. *Haemophilus influenzae* type b invasive disease has been reduced by more than 95% since the introduction of the first conjugate vaccines.

However, substantial vaccine-preventable morbidity and mortality continue to occur among adults from vaccine-preventable diseases, such as hepatitis A, hepatitis B, influenza, and pneumococcal infections. For example, in adults in the United States, there are an estimated 50,000–70,000 deaths annually from influenza, hepatitis B, and invasive pneumococcal disease. Influenza vaccination is recommended for adults age 50 and older, and it has been documented that annual influenza immunization with inactivated vaccine (administered intramuscularly) prevents cardiovascular morbidity and all-cause mortality in persons with coronary and other atherosclerotic vascular disease. Rates of influenza vaccination have increased. Self-reported rates of influenza vaccine coverage in adults older than 65 years increased from 30% in 1989 to 70% in 2004. However, vaccination rates were higher for non-Hispanic whites compared with other ethnic minority groups.

The American College of Physicians recommends that clinicians should review each adult's immunization status at age 50; assess risk factors that would indicate a need for pneumococcal vaccination and annual influenza immunizations; reimmunize at age 65 those who received an immunization against pneumococcus more than 6 years before; ensure that all adults have completed a primary diphtheria-tetanus immunization series, and administer a single booster at age 50; and assess the postvaccination serologic response to hepatitis B vaccination in all recipients who have ongoing risks of exposure to blood or body fluids (eg, sharp injuries, blood splashes).

Strategies have also been proposed to improve influenza, pneumococcal polysaccharide, and hepatitis B vaccination. Strategies to enhance vaccinations in general include increasing community demand for vaccinations; enhancing access to vaccination services; and provider- or system-based interventions, such as reminder systems. Increasing reports of pertussis among US adolescents, adults, and their infant contacts have stimulated vaccine development for older age groups. A safe and effective tetanus-diphtheria 5-component acellular pertussis vaccine (Tdap) is available for use in adolescents and in adults younger than age 65. The Advisory Committee on Immunization Practices (ACIP) recommends routine use of a single dose of Tdap for adults aged 19–64 years to replace the next booster dose of tetanus and diphtheria toxoids vaccine (Td). Further research is needed to elucidate the role of vaccination in persons older than 65 years and to determine whether future booster doses of Tdap are needed.

A new recombinant protein hepatitis E vaccine has been developed that has proven safe and efficacious in preventing hepatitis E among high-risk populations (such as those in Nepal). Both hepatitis A vaccine and immune globulin provide protection against hepatitis A; however, administration of immune globulin may provide a modest benefit over vaccination in some settings.

Recommended immunization schedules for children and adolescent and adults are set forth in Tables 30–12 and 30–13. Thimerosal-free hepatitis B vaccination is available for newborns and infants, and despite the disproved relationship between vaccines and autism, thimerosal-free vaccines are available for pregnant women.

Human papillomavirus (HPV) virus-like particle (VLP) vaccines have demonstrated effectiveness in preventing persistent HPV infections, and thus may impact the rate of cervical intraepithelial neoplasia II–III. The American Cancer Society and the American Academy of Pediatrics (AAP) recommends routine HPV vaccination for girls aged 11–12 years. The AAP also recommends that all unvaccinated girls and women ages 13–26 years receive the HPV vaccine. Trials demonstrate efficacy of bivalent HPV (16/18) or quadrivalent HPV (6/11/16/18)L1 virus-like particle vaccines in preventing new HPV infection and cervical lesions but not in women with preexisting infection. It is estimated that routine use of HPV vaccination of females at 11 to 12 years of age and catch-up vaccination of females at age 13–16 (with vaccination of girls age 9 and 10 at the discretion of the physician) could prevent 95% to 100% of CIN and adenocarcinoma in situ, 99% of genital warts and approximately 70% of cervical cancer cases worldwide; thus, the role of HPV testing will need redefinition. Despite the effectiveness of the vaccine, rates of immunization are low. Interventions addressing personal beliefs and system barriers to vaccinations may help address the slow adoption of this vaccine.

Persons traveling to countries where infections are endemic should take precautions described in Chapter 30: Common Problems in Infectious Diseases & Antimicrobial Therapy. Immunization registries—confidential, population-based, computerized information systems that collect vaccination data about all residents of a geographic area—can be used to increase and sustain high vaccination coverage.

Skin testing for tuberculosis and treating selected patients reduce the risk of reactivation tuberculosis (see

Table 9–11). Two blood tests, which are not confounded by prior BCG (bacille Calmette-Guérin) vaccination, have been developed to detect tuberculosis infection by measuring in vitro T-cell interferon-gamma release in response to two antigens (the enzyme-linked immunospot [ELISpot], [T-SPOT.TB] and the other, a quantitative ELISA [QuantiFERON-TBGold] test). These T-cell–based assays have an excellent specificity that is higher than tuberculin skin testing in BCG-vaccinated populations. The rate of tuberculosis in the United States has been declining since 1992, although this decline has slowed in recent years. In 2007, the tuberculosis rate was the lowest recorded since national reporting began in 1953. The Advisory Council for the Elimination of Tuberculosis has called for a renewed commitment to eliminating tuberculosis in the United States, and the Institute of Medicine has published a detailed plan for achieving that goal. Patients with HIV infection are at an especially high risk for tuberculosis, and tuberculosis preventive therapy in the era of HIV will require further work to overcome implementation barriers and to identify optimal duration of preventive therapy and treatment approach for individuals receiving highly active antiretroviral therapy (HAART).

Treatment of tuberculosis poses a risk of hepatotoxicity and thus requires close monitoring of liver transaminases. Alanine aminotransferase (ALT) monitoring during the treatment of latent tuberculosis infection is recommended for certain individuals (preexisting liver disease, pregnancy, chronic alcohol consumption). ALT should be monitored in HIV-infected patients during treatment of tuberculosis disease and should be considered in patients over the age of 35. Symptomatic patients with an ALT elevation three times the upper limit of normal (ULN) or asymptomatic patients with an elevation five times the ULN should be treated with a modified or alternative regimen.

HIV infection is now the major infectious disease problem in the world, and it affects 850,000–950,000 persons in the United States. Since sexual contact is a common mode of transmission, primary prevention relies on eliminating unsafe sexual behavior by promoting abstinence, later onset of first sexual activity, decreased number of partners, and use of latex condoms. Appropriately used, condoms can reduce the rate of HIV transmission by nearly 70%. In one study, couples with one infected partner who used condoms inconsistently had a considerable risk of infection: the rate of seroconversion was estimated to be 13% after 24 months. No seroconversions were noted with consistent condom use. Unfortunately, as many as one-third of HIV-positive persons continue unprotected sexual practices after learning that they are HIV-infected. Tailored group educational intervention focused on practicing "safer sex" can reduce their transmission-risk behaviors with partners who are not HIV-positive. Other approaches to prevent HIV infection include treatment of sexually transmitted diseases, development of vaginal microbicides, and vaccine development. Increasingly, cases of HIV infection are transmitted by injection drug use. HIV prevention activities should include provision of sterile injection equipment for these individuals.

With regard to secondary prevention, many HIV-infected persons in the United States receive the diagnosis at advanced stages of immunosuppression, and almost all will progress to AIDS if untreated. On the other hand, HAART substantially reduces the risk of clinical progression or death in patients with advanced immunosuppression. Screening tests for HIV are extremely (> 99%) accurate. While the benefits of HIV screening appear to outweigh its harms, current screening is generally based on individual patient risk factors. Such screening can identify persons at risk for AIDS but misses a substantial proportion of those infected. Nonetheless, the yield from screening higher prevalence populations is substantially greater than that from screening the general population, and more widespread screening of the population remains controversial.

In immunocompromised patients, live vaccines are contraindicated but many killed or component vaccines are safe and recommended. *Asymptomatic* HIV-infected patients have not shown adverse consequences when given live MMR and influenza vaccinations as well as tetanus, hepatitis B, *H influenzae* type b, and pneumococcal vaccinations—all should be given. However, if poliomyelitis immunization is required, the inactivated poliomyelitis vaccine is indicated. In *symptomatic* HIV-infected patients, live virus vaccines such as MMR should generally be avoided, but annual influenza vaccination is safe.

Whenever possible, immunizations should be completed before procedures that require or induce immunosuppression (organ transplantation or chemotherapy), or that reduce immunogenic responses (splenectomy). However, if this is not possible, the patient may mount only a partial immune response, yet even this partial response can be beneficial. Patients who undergo allogeneic bone marrow transplantation lose preexisting immunities and should be revaccinated. In many situations, family members should also be vaccinated to protect the immunocompromised patient, although oral live polio vaccine should be avoided because of the risk of infecting the patient.

New cases of poliomyelitis have been reported in the United States, Haiti, and the Dominican Republic recently, slowing its eradication in the Western

Hemisphere. Worldwide eradication of poliovirus, including endemic areas such as India, remains challenging.

The current epidemic of highly pathogenic H5N1 avian influenza within duck and poultry populations in Southeast Asia raises serious concerns that genetic reassortment will result in a human influenza pandemic. In 2003 through 2005, there were 138 confirmed cases of human infection with H5N1 avian influenza in Vietnam, Thailand, Indonesia, China, and Cambodia, with a mortality rate of > 50%. To prevent and prepare for an increase in human cases, public health officials are working to improve detection methods and to stockpile effective antivirals, such as oseltamivir. The development of an H5N1 vaccine is underway. Two trials have demonstrated development of neutralizing antibodies using a vaccine with varying doses of hemagglutinin antigen.

Herpes zoster, caused by reactivation from previous varicella zoster virus (VZV) infection, affects many older adults and people with immune system dysfunction. Whites are at higher risk than other ethnic groups and the incidence in adults age 65 and older may be higher than previously described. It can cause postherpetic neuralgia, a potentially debilitating chronic pain syndrome. A varicella vaccine is available for the prevention of herpes zoster. Several clinical trials have shown that this vaccine (Zostavax) is safe, elevates VZV-specific cell-mediated immunity, and significantly reduces the incidence of herpes zoster and postherpetic neuralgia in persons older than 60 years. In one randomized, double-blind, placebo-controlled trial among more than 38,000 older adults, the vaccine reduced the incidence of postherpetic neuralgia by 66% and the incidence of herpes zoster by 51%. The vaccine is administered as a one-time subcutaneous dose (0.65 mL) and is approved for adults 60 years of age and older. However, durability of vaccine response and whether any booster vaccination is needed are still uncertain. The cost effectiveness of the vaccine varies substantially, and the patient's age should be considered in vaccine recommendations. One study reported a cost-effectiveness exceeding $100,000 per quality-adjusted life year saved.

In 2008, the United States Preventive Services Task Force (USPSTF) reviewed evidence to reaffirm its recommendation on screening for asymptomatic bacteriuria in adults. New evidence was reviewed, which continues to support routine screening in pregnant women but not in other groups of adults.

Prevention of Cardiovascular Disease

Cardiovascular diseases, including coronary heart disease (CHD) and stroke, represent two of the most important causes of morbidity and mortality in developed countries. Several risk factors increase the risk for coronary disease and stroke. They can be divided into those that are modifiable (eg, lipid disorders, hypertension, cigarette smoking) and those that are not (eg, gender, age, family history of early coronary disease). This section considers the role of screening for and treating modifiable risk factors.

Impressive declines in age-specific mortality rates from heart disease and stroke have been achieved in all age groups in North America during the past 2 decades. The chief reasons for this favorable trend appear to be modification of risk factors, especially cigarette smoking and hypercholesterolemia, plus more aggressive detection and treatment of hypertension and better care for patients with heart disease. African Americans appear to have a greater proportion of risk attributable to these key risk factors, suggesting that focusing on better control could help reduce disparities in health outcomes.

Abdominal Aortic Aneurysm

Screening for abdominal aortic aneurysm in men aged 65–75 years is associated with a significant reduction in condition-specific mortality (odds ratio, 0.57 [95% CI, 0.45 to 0.74]). This benefit is sustained through 7 years of follow-up. Women do not appear to benefit, and most of the benefit in men appears to accrue among current or former smokers.

Fleming C et al. Screening for abdominal aortic aneurysm: a best-evidence systematic review for the U.S. Preventive Services Task Force. Ann Intern Med. 2005 Feb 1;142(3):203–11. [PMID: 15684209]

Cigarette Smoking

Cigarette smoking remains the most important cause of preventable morbidity and early mortality. In 2000, there were an estimated 4.8 million premature deaths in the world attributable to smoking, 2.4 million in developing countries and 2 million in industrialized countries. More than three-quarters (3.8 million) of these deaths were in men. The leading causes of death from smoking were cardiovascular diseases (1.7 million deaths), chronic obstructive pulmonary disease (COPD) (1 million deaths), and lung cancer (0.9 million deaths). Nicotine is highly addictive, raises brain levels of dopamine, and produces withdrawal symptoms on discontinuation. Cigar smoking has also increased; there is also continued use of smokeless tobacco (chewing tobacco and snuff), particularly among young people. Tobacco dependence may have a genetic component.

Cigarettes are responsible for one in every five deaths in the United States, yet smoking prevalence rates have been increasing among high school and college students. Currently, 23% of US adults and 26% of US young adults are smokers.

Smokers have twice the risk of fatal heart disease, 10 times the risk of lung cancer, and several times the risk of cancers of the mouth, throat, esophagus, pancreas, kidney, bladder, and cervix; a twofold to threefold higher incidence of stroke and peptic ulcers (which heal less well than in nonsmokers); a twofold to fourfold greater risk of fractures of the hip, wrist, and vertebrae; four times the risk of invasive pneumococcal disease; and a twofold increase in cataracts. In the United States, over 90% of cases of COPD occur among current or former smokers. Both active smoking and passive smoking are associated with deterioration of the elastic properties of the aorta (increasing the risk of aortic aneurysm) and with progression of carotid artery atherosclerosis. Smoking has also been associated with increased risks of leukemia, of colon and prostate cancers, of breast cancer among postmenopausal women who are slow acetylators of *N*-acetyltransferase-2 enzymes, osteoporosis, and Alzheimer's disease. In cancers of the head and neck, lung, esophagus, and bladder, smoking is linked to mutations of the *P53* gene, the most common genetic change in human cancer. Patients with head and neck cancer who continue to smoke during radiation therapy have lower rates of response than those who do not smoke. Olfaction and taste are impaired in smokers, and facial wrinkles are increased. Heavy smokers have a 2.5 greater risk of age-related macular degeneration. Smokers die 5–8 years earlier than never-smokers.

The children of smokers have lower birth weights, are more likely to be mentally retarded, have more frequent respiratory infections and less efficient pulmonary function, have a higher incidence of chronic ear infections than children of nonsmokers, and are more likely to become smokers themselves.

In addition, exposure to environmental tobacco smoke has been shown to increase the risk of cervical cancer, lung cancer, invasive pneumococcal disease, and heart disease; to promote endothelial damage and platelet aggregation; and to increase urinary excretion of tobacco-specific lung carcinogens. The incidence of breast cancer may be increased as well. Of approximately 450,000 smoking-related deaths in the United States annually, as many as 53,000 are attributable to environmental tobacco smoke.

Smoking cessation reduces the risks of death and of myocardial infarction in people with coronary artery disease; reduces the rate of death and acute myocardial infarction in patients who have undergone percutaneous coronary revascularization; lessens the risk of stroke; slows the rate of progression of carotid atherosclerosis; and is associated with improvement of COPD symptoms. On average, women smokers who quit smoking by age 35 add about 3 years to their life expectancy, and men add more than 2 years to theirs. Smoking cessation can increase life expectancy even for those who stop after the age of 65.

Although tobacco use constitutes the most serious common medical problem, it is undertreated. Almost 40% of smokers attempt to quit each year, but only 4% are successful. Factors associated with successful cessation include having a rule against smoking in the home, being older, and having greater education. Persons whose physicians advise them to quit are 1.6 times as likely to attempt quitting. Over 70% of smokers see a physician each year, but only 20% of them receive any medical quitting advice or assistance.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Several effective interventions are available to promote smoking cessation, including counseling, pharmacotherapy, and combinations of the two. The five steps for helping smokers quit are summarized in Table 1–3. Common elements of supportive smoking cessation treatments are reviewed in Table 1–4. A system should be implemented to identify smokers, and advice to quit should be tailored to the patient's level of readiness to change. Pharmacotherapy to reduce cigarette consumption is ineffective in smokers who are unwilling or not ready to quit. Conversely, all patients trying to quit should be offered pharmacotherapy except those with medical contraindications, women who are pregnant or breast-feeding, and adolescents.

Table 1–3. Actions and strategies for the primary care clinician to help patients quit smoking.

Action	**Strategies for Implementation**

Step 1. Ask—Systematically Identify All Tobacco Users at Every Visit	
Implement an officewide system that ensures that for *every* patient at *every* clinic visit, tobacco-use status is queried and documented[1]	Expand the vital signs to include tobacco use.
	Data should be collected by the health care team.
	The action should be implemented using preprinted progress note paper that includes the expanded vital signs, a vital signs stamp or, for computerized records, an item assessing tobacco-use status.
	Alternatives to the vital signs stamp are to place tobacco-use status stickers on all patients' charts or to indicate smoking status using computerized reminder systems.
Step 2. Advise—Strongly Urge All Smokers to Quit	
In a *clear*, *strong*, and *personalized* manner, urge every smoker to quit	Advice should be
	Clear:"I think it is important for you to quit smoking now, and I will help you. Cutting down while you are ill is not enough."

	Strong:"As your clinician, I need you to know that quitting smoking is the most important thing you can do to protect your current and future health."
	Personalized: Tie smoking to current health or illness and/or the social and economic costs of tobacco use, motivational level/readiness to quit, and the impact of smoking on children and others in the household.
	Encourage clinic staff to reinforce the cessation message and support the patient's quit attempt.
Step 3. Attempt—Identify Smokers Willing to Make a Quit Attempt	
Ask every smoker if he or she is willing to make a quit attempt at this time	If the patient is willing to make a quit attempt at this time, provide assistance (see step 4).
	If the patient prefers a more intensive treatment or the clinician believes more intensive treatment is appropriate, refer the patient to

	interventions administered by a smoking cessation specialist and follow up with him or her regarding quitting (see step 5).
	If the patient clearly states he or she is not willing to make a quit attempt at this time, provide a motivational intervention.
Step 4. Assist—Aid the Patient in Quitting	
A. Help the patient with a quit plan	*Set a quit date*. Ideally, the quit date should be within 2 weeks, taking patient preference into account.
	Help the patient prepare for quitting. The patient must:
	Inform family, friends, and coworkers of quitting and request understanding and support.
	Prepare the environment by removing cigarettes from it. Prior to quitting, the patient should avoid smoking in places where he or she spends a lot of time (eg, home, car).
	Review previous quit attempts.

	What helped? What led to relapse?
	Anticipate challenges to the planned quit attempt, particularly during the critical first few weeks.
B. Encourage nicotine replacement therapy except in special circumstances	Encourage the use of the nicotine patch or nicotine gum therapy for smoking cessation (see Table 1–5, Table 1–6, and Table 1–7 for specific instructions and precautions).
C. Give key advice on successful quitting	***Abstinence:*** Total abstinence is essential. Not even a single puff after the quit date.
	Alcohol: Drinking alcohol is highly associated with relapse. Those who stop smoking should review their alcohol use and consider limiting or abstaining from alcohol use during the quit process.
	Other smokers in the household: The presence of other smokers in the household, particularly a spouse, is

	associated with lower success rates. Patients should consider quitting with their significant others and/or developing specific plans to maintain abstinence in a household where others still smoke.
D. Provide supplementary materials	***Source:*** Federal agencies, including the National Cancer Institute and the Agency for Health Care Policy and Research; nonprofit agencies (American Cancer Society, American Lung Association, American Heart Association); or local or state health departments.
	Selection concerns: The material must be culturally, racially, educationally, and age appropriate for the patient.
	Location: Readily available in every clinic office.
Step 5. Arrange—Schedule Follow-Up Contact	
Schedule follow-up contact, either in person	***Timing:*** Follow-up contact should occur soon after the quit

or via telephone[1]	date, preferably during the first week. A second follow-up contact is recommended within the first month. Schedule further follow-up contacts as indicated.
	Actions during follow-up: Congratulate success. If smoking occurred, review the circumstances and elicit recommitment to total abstinence. Remind the patient that a lapse can be used as a learning experience and is not a sign of failure. Identify the problems already encountered and anticipate challenges in the immediate future. Assess nicotine replacement therapy use and problems. Consider referral to a more intense or specialized program.

[1] Repeated assessment is not necessary in the case of the adult who has never smoked or not smoked for many years and for whom the information is clearly

documented in the medical record.

Adapted and reproduced, with permission, from: The Agency for Health Care Policy and Research. Smoking Cessation Clinical Practice Guideline. JAMA. 1996 Apr 24;275(16):1270–80.

Table 1–4. Common elements of supportive smoking treatments.

Component	**Examples**
Encouragement of the patient in the quit attempt	Note that effective cessation treatments are now available.
	Note that half the people who have *ever* smoked have now quit.
	Communicate belief in the patient's ability to quit.
Communication of caring and concern	Ask how the patient feels about quitting.
	Directly express concern and a willingness to help.
	Be open to the patient's expression of fears of quitting, difficulties experienced, and ambivalent feelings.

Encouragement of the patient to talk about the quitting process	Ask about
	Reasons that the patient wants to quit.
	Difficulties encountered while quitting.
	Success the patient has achieved.
	Concerns or worries about quitting.
Provision of basic information about smoking and successful quitting	Inform the patient about
	The nature and time course of withdrawal.
	The addictive nature of smoking.
	The fact that any smoking (even a single puff) increases the likelihood of full relapse.

Adapted, with permission, from: The Agency for Health Care Policy and Research. Smoking Cessation Clinical Practice Guideline. JAMA. 1996 Apr 24;275(16):1270–80.

Several pharmacologic therapies have been shown to be effective in promoting cessation. Nicotine replacement therapy doubles the chance of successful quitting. Guidelines for its use are presented in Table 1–5. Suggestions for the nicotine patch are listed in Table 1–6 and for nicotine gum in Table 1–7. The nicotine patch, gum, and lozenges are available over-the-counter, and nicotine nasal spray and inhalers by prescription. When the spray is combined with the patch, cessation rates are substantially higher. The sustained-release antidepressant drug bupropion (150–300 mg/d orally) is an effective smoking cessation agent and is associated with minimal weight gain, although seizures are a contraindication. It acts by boosting brain levels of dopamine and norepinephrine, mimicking the effect of nicotine. Weight gain was less in the combined program (Table 1–8). More recently, varenicline, a partial nicotinic acetylcholine-receptor agonist, has shown promise as an effective agent, although its adverse effects are incompletely understood. No single pharmacotherapy is clearly more effective than others, so patient preferences should be taken into account in selecting a treatment.

Table 1–5. Clinical guidelines for prescribing nicotine replacement products.
1. Who should receive nicotine replacement therapy?
Available research shows that nicotine replacement therapy generally increases rates of smoking cessation.

Therefore, except in special circumstances, the clinician should encourage the use of nicotine replacement with patients who smoke. Little research is available on the use of nicotine replacement with light smokers (ie, those smoking 10–15 cigarettes/d). If nicotine replacement is to be used with light smokers, a lower starting dose of the nicotine patch or nicotine gum should be considered.
2. Should nicotine replacement therapy be tailored to the individual smoker?
Research does not support the tailoring of nicotine patch therapy (except with light smokers as noted above). Patients should be prescribed the patch dosages outlined in Table 1–6.
Research supports tailoring nicotine gum treatment. Specifically, research suggests that 4-mg gum rather than 2-mg gum be used with patients who are highly dependent on nicotine (eg, those smoking > 20 cigarettes/d, those who smoke immediately upon awakening, and those who report histories of severe nicotine withdrawal symptoms). Clinicians may also recommend the higher gum dose if patients request it or have failed to quit using the 2-mg gum.

Adapted with permission, from: The Agency for Health Care Policy and Research. Smoking Cessation Clinical Practice Guideline. JAMA. 1996 Apr 24;275(16):1270–

Table 1–6. Suggestions for the clinical use of the nicotine patch.

Parameter of Clinical Use	**Suggestions**
Patient selection	Appropriate as a primary pharmacotherapy for smoking cessation.
Precautions	*Pregnancy:* Pregnant smokers should first be encouraged to attempt cessation without pharmacologic treatment. The nicotine patch should be used during pregnancy only if the increased likelihood of smoking cessation, with its potential benefits, outweighs the risk of nicotine replacement and potential concomitant smoking. Similar factors should be considered in lactating women.
	Cardiovascular diseases: While not an independent risk factor for acute myocardial events, the nicotine patch should be used only after consideration of risks and benefits among particular cardiovascular patient groups: those in the immediate (within 2 weeks) post-

<table>
<tr><td></td><td colspan="3">myocardial infarction period, those with serious arrhythmias, and those with severe or worsening angina pectoris.</td></tr>
<tr><td></td><td colspan="3"><i>Skin reactions:</i> Up to 50% of patients using the nicotine patch will have a local skin reaction. Skin reactions are usually mild and self-limiting but may worsen over the course of therapy. Local treatment with hydrocortisone cream (2.5%) or triamcinolone cream (0.5%) and rotating patch sites may ameliorate such local reactions. In fewer than 5% of patients do such reactions require the discontinuation of nicotine patch treatment.</td></tr>
<tr><td rowspan="2">Dosage[1]</td><td colspan="3">Treatment of 8 weeks or less has been shown to be as efficacious as longer treatment periods. Based on this finding, we suggest the following treatment schedules as reasonable for most smokers. Clinicians should consult the package insert for other treatment suggestions. Finally, clinicians should consider individualizing treatment based on specific patient characteristics such as previous experience with the patch, number of cigarettes smoked, and degree of addiction.</td></tr>
<tr><td>Brand</td><td>Duration</td><td>Dosage</td></tr>
</table>

		(weeks)	**(mg/h)**
	Nicoderm and Habitrol	4	21/24
		then 2	14/24
		then 2	7/24
	Prostep	4	22/24
		then 4	11/24
	Nicotrol	4	15/16
		then 2	10/16
		then 2	5/16
Prescribing instructions	*Abstinence from smoking:* The patient should refrain from smoking while using the patch.		
	Location: At the start of each day, the patient should place a new patch on a relatively hairless location between the neck and the waist.		
	Activities: There are no restrictions while using the patch.		
	Time: Patches should be applied as soon as patients awaken on their quit day.		

[1] These dosage recommendations are based on a review of the published research literature and do not necessarily conform to package insert information.

Reproduced, with permission, from: The Agency for Health Care Policy and Research. Smoking Cessation Clinical Practice Guideline. JAMA. 1996 Apr 24;275(16):1270–80. Updated and revised, with permission, from Treating Tobacco Use and Dependence. U.S. Public Health Service. http://www.surgeongeneral.gov/tobacco/systems.htm

Table 1–7. Suggestions for the clinical use of nicotine gum.

Parameter of Clinical Use	**Suggestions**
Patient selection	Appropriate as a primary pharmacotherapy for smoking cessation.
Precautions	*Pregnancy:* Pregnant smokers should first be encouraged to attempt cessation without pharmacologic treatment. Nicotine gum should be used during pregnancy only if the increased likelihood of smoking cessation, with its potential benefits, outweighs the risk of nicotine replacement and potential concomitant smoking.
	Cardiovascular diseases: Although not an independent risk factor for acute myocardial events, nicotine gum should be

	used only after consideration of risks and benefits among particular cardiovascular patient groups: those in the immediate (within 2 weeks) post-myocardial infarction period, those with serious arrhythmias, and those with serious or worsening angina pectoris.
	Adverse effects: Common adverse effects of nicotine chewing gum include mouth soreness, hiccups, dyspepsia, and jaw ache. These effects are generally mild and transient and can often be alleviated by correcting the patient's chewing technique (see "Prescribing instructions" below).
Dosage	*Dosage:* Nicotine gum is available in doses of 2 mg and 4 mg per piece. Patients who smoke less than 25 cigarettes per day should be prescribed the 2-mg gum initially. The 4-mg gum should be prescribed to patients who express a preference for it, have failed with the 2-mg gum but remain motivated to quit, and/or smoke more than 25 cigarettes per day. The gum is most commonly prescribed for the first few months of a quit attempt. Clinicians should tailor the duration of therapy to fit the needs of each patient.

	Patients using the 2-mg strength should use not more than 30 pieces per day, whereas those using the 4-mg strength should not exceed 20 pieces per day.
Prescribing instructions	*Abstinence from smoking:* The patient should refrain from smoking while using the gum.
	Chewing technique: The gum should be chewed slowly until a "peppery" taste emerges, then "parked" between cheek and gum to facilitate nicotine absorption through the oral mucosa. Gum should be slowly and intermittently chewed and parked for about 30 minutes.
	Absorption: Acidic beverages (eg, coffee, juices, soft drinks) interfere with the buccal absorption of nicotine, so eating and drinking anything except water should be avoided for 15 minutes before and during chewing.
	Scheduling of dose: A common problem is that patients do not use enough gum to get the maximum benefit: they chew too few pieces per day and do not use the gum for a sufficient number of weeks. Instructions to chew the gum on a fixed schedule (at least 1 piece every 1 to 2 hours) for at least

	1 to 3 months may be more beneficial than ad lib use.

Reproduced, with permission, from: The Agency for Health Care Policy and Research. Smoking Cessation Clinical Practice Guideline. JAMA. 1996 Apr 24;275(16):1270–80. Updated and revised, with permission, from Treating Tobacco Use and Dependence. U.S. Public Health Service. http://www.surgeongeneral.gov/tobacco/systems.htm

Table 1–8. Suggestions for the clinical use of bupropion SR.

Parameter of Clinical Use	**Suggestions**
Patient selection	Appropriate as a first-line pharmacotherapy for smoking cessation.
Precautions	*Pregnancy:* Pregnant smokers should be encouraged to quit first without pharmacologic treatment. Bupropion SR should be used during pregnancy only if the increased likelihood of smoking abstinence, with its potential benefits, outweighs the risk of bupropion SR treatment and

	potential concomitant smoking. Similar factors should be considered in lactating women (FDA Class B).
	Cardiovascular diseases: Generally well tolerated; infrequent reports of hypertension.
	Side effects: The most common side effects reported by bupropion SR users were insomnia (35–40%) and dry mouth (10%).
	Contraindications: Bupropion SR is contraindicated in individuals with a history of seizure disorder, a history of an eating disorder, who are using another form of bupropion (Wellbutrin or Wellbutrin SR), or who have used an MAO inhibitor in the past 14 days.
Dosage	Patients should begin with a dose of 150 mg every morning for 3 days, then increase to 150 mg twice daily. Dosing at 150 mg twice daily should continue for 7–12 weeks following the quit date. Unlike nicotine replacement products, patients should begin bupropion SR treatment 1–2 weeks before they quit smoking. For maintenance therapy, consider bupropion SR 150 mg twice daily for up to 6 months.

Prescribing instructions	*Cessation prior to quit date:* Recognize that some patients will lose their desire to smoke prior to their quit date, or will spontaneously reduce the amount they smoke.
	Scheduling of dose: If insomnia is marked, taking the evening dose earlier (in the afternoon, at least 8 hours after the first dose) may provide some relief.
	Alcohol: Use alcohol only in moderation.

MAO = monoamine oxidase inhibitor.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Weight gain occurs in most patients (80%) following smoking cessation. For many it averages 2 kg, but for others (10–15%) major weight gain—over 13 kg—may occur.

Clinicians should not show disapproval of patients who have not stopped smoking or who are not ready to make a quit attempt. Thoughtful advice that emphasizes the benefits of cessation and recognizes common barriers to success can increase motivation to quit and quit rates. An intercurrent illness such as acute bronchitis or acute myocardial infarction may motivate even the most addicted smoker to quit. Individualized or group counseling is very cost-effective, even more so than treating hypertension. Smoking cessation counseling by telephone ("quitlines") has proved effective. An additional strategy is to recommend that any smoking take place out of doors to limit the effects of passive smoke on housemates and coworkers. This can lead to smoking reduction and quitting. The clinician's role in smoking cessation is summarized in Table 1–3. Public policies, including higher cigarette taxes and more restrictive public smoking laws, have also been shown to encourage cessation.

Lipid Disorders

Higher low-density lipoprotein (LDL) cholesterol concentrations and lower high-density lipoprotein (HDL) levels are associated with an increased risk of CHD. Elevated triglyceride levels and elevated plasma lipoprotein(a) are also independent risk factors for CHD. The absolute benefits of screening for—and treating—abnormal lipid levels depend on the presence and number of other cardiovascular risk factors. If other risk factors are present, cardiovascular risk is higher and the benefits of therapy are greater. Patients with diabetes mellitus or known cardiovascular disease are at still higher risk and benefit from treatment even when lipid levels are normal.

Evidence for the effectiveness of statin-type drugs is better than for the other classes of lipid-lowering agents or dietary changes specifically for improving lipid levels. Multiple large randomized, placebo-controlled trials have demonstrated important reductions in total mortality, major coronary events, and strokes with lowering levels of LDL cholesterol by statin therapy for patients with known cardiovascular disease. Statins also reduce cardiovascular events for patients with diabetes mellitus. For patients with no previous history of cardiovascular events or diabetes, statins reduce coronary events for men, but less data are available for women. The recent JUPITER trial, however, showed relatively similar benefit for both men and women.

Guidelines for therapy are discussed in Chapter 28: Lipid Disorders.

analysis of randomized controlled trials. Arch Intern Med. 2006 Nov 27;166(21):2307–13. [PMID: 17130382]

Hypertension

Over 43 million adults in the United States have hypertension, but 31% are unaware of their elevated blood pressure; 17% are aware but untreated; 29% are being treated but have not controlled their blood pressure (still greater than 140/90 mm Hg); and only 23% are well controlled. In every adult age group, higher values of systolic and diastolic blood pressure carry greater risks of stroke and congestive heart failure. Systolic blood pressure is a better predictor of morbid events than diastolic blood pressure. Home monitoring is better correlated with target organ damage than clinic-based values. Clinicians can apply specific blood pressure criteria, such as those of the Joint National Committee, along with consideration of the patient's cardiovascular risk, to decide at what levels treatment should be considered in individual cases. Table 11–1 presents a classification of hypertension based on blood pressures.

Primary prevention of hypertension can be accomplished by strategies aimed at both the general population and special high-risk populations. The latter include persons with high-normal blood pressure or a family history of hypertension, blacks, and individuals with various behavioral risk factors such as physical inactivity; excessive consumption of salt, alcohol, or calories; and deficient intake of potassium. Effective interventions for primary prevention of hypertension include reduced sodium and alcohol consumption, weight loss, and regular exercise. Potassium supplementation lowers blood pressure modestly, and a diet high in fresh fruits and vegetables and low in fat, red meats, and sugar-containing beverages also reduces blood pressure. Interventions of unproven efficacy include pill supplementation of potassium, calcium, magnesium, fish oil, or fiber; macronutrient alteration; and stress management.

Improved identification and treatment of hypertension is a major cause of the recent decline in stroke deaths. Because hypertension is usually asymptomatic, screening is strongly recommended to identify patients for treatment. Despite strong recommendations in favor of screening and treatment, hypertension control remains suboptimal. An intervention that included patient education and provider education was more effective than provider education alone in achieving control of hypertension, suggesting the benefits of patient participation. Pharmacologic management of hypertension is discussed in Chapter 11: Systemic Hypertension.

Chemoprevention

As discussed in Chapter 10: Heart Disease and Chapter 24: Nervous System Disorders, regular use of low-dose aspirin (81–325 mg) can reduce the incidence of myocardial infarction in men. Low-dose aspirin reduces stroke but not myocardial infarction in middle-aged women. Based on its ability to prevent cardiovascular events, aspirin use is cost-effective for men and women who are at increased risk. Nonsteroidal anti-inflammatory drugs may reduce the incidence of colorectal adenomas and polyps but may also increase heart disease and gastrointestinal bleeding, and thus are not recommended for colon cancer prevention in average risk patients. Antioxidant vitamin (vitamin E, vitamin C, and beta-carotene) supplementation produced no significant reductions in the 5-year incidence of—or mortality from—vascular disease, cancer, or other major outcomes in high-risk individuals with coronary artery disease, other occlusive arterial disease, or diabetes mellitus.

Prevention of Osteoporosis

Osteoporosis, characterized by low bone mineral density, is common and associated with an increased risk of fracture. The lifetime risk of an osteoporotic fracture is approximately 50% for women and 30% for men. Osteoporotic fractures can cause significant pain and disability. As such, research has focused on means of preventing osteoporosis and related fractures. Primary prevention strategies include calcium supplementation, vitamin D supplementation, and exercise programs. A recent systematic review and meta-analysis found that calcium supplementation of 1200 mg per day or more (with or without vitamin D) could decrease fracture risk for adults (mainly women were studied) over age 50. Screening for osteoporosis on the basis of low bone mineral density is also recommended for women over age 60, based on indirect evidence that screening can identify women with low bone mineral density and that treatment of women with low bone density with bisphosphonates is effective in reducing fractures. The effectiveness of screening for osteoporosis in younger women and in men has not been established. In addition, real-world adherence to pharmacologic therapy for osteoporosis is low: one-third to one-half of patients do not take their medication as directed. Vitamin D deficiency is common and can increase the risk of fracture. Screening to detect vitamin D deficiency in older adults has been proposed, but has not yet been rigorously evaluated.

Prevention of Physical Inactivity

Lack of sufficient physical activity is the second most important contributor to preventable deaths, trailing only tobacco use. A sedentary lifestyle has been linked to 28% of deaths from leading chronic diseases. The Centers for Disease Control and Prevention (CDC) has recommended that every adult in the United States should engage in 30 minutes or more of moderate-intensity physical activity on most days of the week. This guideline complements previous advice urging at least 20–30 minutes of more vigorous aerobic exercise three to five times a week.

Patients who engage in regular moderate to vigorous exercise have a lower risk of myocardial infarction, stroke, hypertension, hyperlipidemia, type 2 diabetes mellitus, diverticular disease, and osteoporosis. Current evidence supports the recommended guidelines of 30 minutes of moderate physical activity on most days of the week in both the primary and secondary prevention of CHD. Between 1980 and 2000, an estimated 5% of the decrease in US deaths from CHD among adults aged 25–84 years resulted from increases in physical activity.

In older nonsmoking men, walking 2 miles or more per day is associated with an almost 50% lower age-related mortality. The relative risk of stroke was found to be less than one-sixth in men who exercised vigorously compared with those who were inactive; the risk of type 2 diabetes mellitus was about half among men who exercised five or more times weekly compared with those who exercised once a week. Glucose control is improved in diabetics who exercise regularly, even at a modest level. In sedentary individuals with dyslipidemia, high amounts of high-intensity exercise produce significant beneficial effects on serum lipoprotein profiles. Physical activity is associated with a lower risk of colon cancer (although not rectal cancer) in men and women and of breast and reproductive organ cancer in women. Finally, weight-bearing exercise (especially resistance and high-impact activities) increases bone mineral content and retards development of osteoporosis in women and contributes to a reduced risk of falls in older persons. Resistance training has been shown to enhance muscular strength, functional capacity, and quality of life in men and women with and without CHD and is endorsed by the

American Heart Association.

Exercise may also confer benefits on those with chronic illness. Men and women with chronic symptomatic osteoarthritis of one or both knees benefited from a supervised walking program, with improved self-reported functional status and decreased pain and use of pain medication. Exercise produces sustained lowering of both systolic and diastolic blood pressure in patients with mild hypertension. In addition, physical activity can help patients maintain ideal body weight. Individuals who maintain ideal body weight have a 35–55% lower risk for myocardial infarction than with those who are obese. Physical activity reduces depression and anxiety; improves adaptation to stress; improves sleep quality; and enhances mood, self-esteem, and overall performance.

In longitudinal cohort studies, individuals who report higher levels of leisure time physical activity are less likely to gain weight. Conversely, individuals who are overweight are less likely to stay active. However, at least 60 minutes of daily moderate-intensity physical activity may be necessary to maximize weight loss and prevent significant weight regain. Moreover, adequate levels of physical activity appear to be important for the prevention of weight gain and the development of obesity. Physical activity also appears to have an independent effect on health-related outcomes such as development of type 2 diabetes mellitus in patients with impaired glucose tolerance when compared with body weight, suggesting that adequate levels of activity may counteract the negative influence of body weight on health outcomes.

However, physical exertion can rarely trigger the onset of acute myocardial infarction, particularly in persons who are habitually sedentary. Increased activity increases the risk of musculoskeletal injuries, which can be minimized by proper warm-up and stretching, and by gradual rather than sudden increase in activity. Other potential complications of exercise include angina pectoris, arrhythmias, sudden death, and asthma. In insulin-requiring diabetics who undertake vigorous exercise, the need for insulin is reduced; hypoglycemia may be a consequence.

Only about 20% of adults in the United States are active at the moderate level—and only 8% currently exercise at the more vigorous level—recommended for health benefits. Instead, 60% report irregular or no leisure time physical activity.

The value of routine electrocardiography stress testing prior to initiation of an exercise program in middle-aged or older adults remains controversial. Patients with ischemic heart disease or other cardiovascular disease require medically supervised, graded exercise programs. Medically supervised exercise prolongs life in patients with congestive heart failure. Exercise should not be prescribed for patients with decompensated congestive heart failure, complex ventricular arrhythmias, unstable angina pectoris, hemodynamically significant aortic stenosis, or significant aortic aneurysm. Five- to 10-minute warm-up and cool-down periods, stretching exercises, and gradual increases in exercise intensity help prevent musculoskeletal and cardiovascular complications.

Physical activity can be incorporated into any person's daily routine. For example, the clinician can advise a patient to take the stairs instead of the elevator, to walk or bike instead of driving, to do housework or yard work, to get off the bus one or two stops earlier and walk the rest of the way, to park at the far end of the parking lot, or to walk during the lunch hour. The basic message should be the more the better and anything is better than nothing.

To be more effective in counseling about exercise, clinicians can also incorporate motivational interviewing techniques, adopt a whole practice approach (eg, use practice nurses to assist), and establish linkages with community agencies. Clinicians can incorporate the "5 As" approach:

1. Ask (identify those who can benefit).
2. Assess (current activity level).
3. Advise (individualize plan).

4. Assist (provide a written exercise prescription and support material).
5. Arrange (appropriate referral and follow up).

Such interventions have a moderate effect on self-reported physical activity and cardiorespiratory fitness, even if they do not always help patients achieve a predetermined level of physical activity. In their counseling, clinicians should advise patients about both the benefits and risks of exercise, prescribe an exercise program appropriate for each patient, and provide advice to help prevent injuries or cardiovascular complications.

Although primary care providers regularly ask patients about physical activity and advise them with verbal counseling, few providers provide written prescriptions or perform fitness assessments. Tailored interventions may potentially help increase physical activity in individuals. Exercise counseling with a prescription, eg, for walking at either a hard intensity or a moderate intensity-high frequency, can produce significant long-term improvements in cardiorespiratory fitness. To be effective, exercise prescriptions must include recommendations on type, frequency, intensity, time, and progression of exercise and must follow disease-specific guidelines. In addition, published research suggests that getting patients to change physical activity levels requires motivational strategies beyond simple exercise instruction including patient education about goal-setting, self-monitoring, and problem-solving. For example, helping patients identify emotionally rewarding and physically appropriate activities, meet contingencies, and find social support will increase rates of exercise continuation.

Some physical activity is always preferable to a sedentary lifestyle. For home-bound elderly who have limited mobility and strength, such physical activity could focus on "functional fitness," such as mobility, transfers, and performing activities of daily living. Exercise-based rehabilitation can protect against falls and fall-related injuries and improve functional performance.

Prevention of Overweight & Obesity

Obesity is now a true epidemic and public health crisis that both clinicians and patients must face. Normal body weight is defined as a body mass index (BMI), calculated as the weight in kilograms divided by the height in meters squared, of < 25 kg/m^2; overweight is defined as a BMI = 25.0–29.9 kg/m^2, and obesity as a BMI > 30 kg/m^2. The prevalence of obesity in US children, adolescents, and adults has grown dramatically since 1990. In 2003–2004, 17% of US children and adolescents were overweight and 32% of adults were obese. Among men, the prevalence of obesity increased significantly between 1999 and 2000 (28%) and between 2003 and 2004 (31%). Among women, no significant increase in the prevalence of obesity was observed between 1999 and 2000 (33%) or between 2003 and 2004 (33%). The prevalence of extreme obesity (BMI 40) in 2003–2004 was 3% in men and 7% in women. Prevalence varies by race and age, with older African American and Latina women having the greatest prevalence of obesity. This trend has been linked both to declines in physical activity and to increased caloric intake in diets rich in fats and carbohydrates.

Adequate levels of physical activity appear to be important for the prevention of weight gain and the development of obesity. However, as noted above, only about 20% of Americans are physically active at a moderate level, and only 8% at a more vigorous level, and 60% report irregular or no leisure time physical activity. In addition, only 3% of Americans meet four of the five recommendations for the intake of grains, fruits, vegetables, dairy products, and meat of the Food Guide Pyramid. Only one of four Americans eats the recommended five or more fruits and vegetables per day.

Risk assessment of the overweight and obese patient begins with determination of BMI, waist circumference for those with a BMI of 35 or less, presence of comorbid conditions, and a fasting blood glucose and lipid panel. Obesity is clearly associated with type 2 diabetes mellitus, hypertension, hyperlipidemia, cancer, osteoarthritis, cardiovascular disease, obstructive sleep apnea, and asthma. One of the most important sequelae of the rapid surge in prevalence of overweight and obesity between 1990 and 2000 has been a dramatic 30–40% increase in the prevalence of type 2 diabetes mellitus. In addition, almost one-quarter of the US population currently has the metabolic syndrome, putting them at high risk for the development of CHD. The relationship between overweight and obesity and diabetes, hypertension, and coronary artery disease is thought to be due to insulin resistance and compensatory hyperinsulinemia. Persons with a BMI 40 have death rates from cancers that are

52% higher for men and 62% higher for women than the rates in men and women of normal weight. Significant trends of increasing risk of death with higher BMIs are observed for cancers of the stomach and prostate in men and for cancers of the breast, uterus, cervix, and ovary in women, and for cancers of the esophagus, colon and rectum, liver, gallbladder, pancreas, and kidney, non-Hodgkin lymphoma, and multiple myeloma in both men and women.

In the Framingham Heart Study, overweight and obesity were associated with large decreases in life expectancy. For example, 40-year-old female nonsmokers lost 3.3 years and 40-year-old male nonsmokers lost 3.1 years of life expectancy because of overweight, and 7.1 years and 5.8 years of life expectancy, respectively, because of obesity. Obese female smokers lost 7.2 years and obese male smokers lost 6.7 years of life expectancy compared with normal-weight smokers, and 13.3 years and 13.7 years, respectively, compared with normal-weight nonsmokers. Clinicians must work to identify and provide the best prevention and treatment strategies for patients who are overweight and obese. Patients with abdominal obesity (high waist to hip size ratio) are at particularly increased risk. Control of visceral obesity in addition to other cardiovascular risk factors (hypertension, insulin resistance, and dyslipidemia) is essential to reducing cardiovascular risk.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Prevention of overweight and obesity involves both increasing physical activity and dietary modification to reduce caloric intake. Clinicians can help guide patients to develop personalized eating plans to reduce energy intake, particularly by recognizing the contributions of fat, concentrated carbohydrates, and large portion sizes (see Chapter 29: Nutritional Disorders). Patients typically underestimate caloric content, especially when consuming food away from home. Providing patients with caloric and nutritional information may help address the current obesity epidemic. To prevent the long-term chronic disease sequelae of overweight or obesity, clinicians must work with patients to modify other risk factors, eg, by smoking cessation (see above) and strict glycemic and blood pressure control (see Chapter 27: Diabetes Mellitus & Hypoglycemia and Systemic Hypertension).

Lifestyle modification, including diet, physical activity, and behavior therapy, has been shown to induce clinically significant weight loss. Other treatment options for obesity include pharmacotherapy and surgery. One potentially effective diet strategy is the replacement of caloric beverages with low-calorie or noncaloric beverages. As noted above, in overweight and obese persons, at least 60 minutes of moderate-high intensity physical activity may be necessary to maximize weight loss and prevent significant weight regain. Counseling interventions or pharmacotherapy can produce modest (3–5 kg) sustained weight loss over 6–12 months. Pharmacotherapy appears safe in the short term; long-term safety is still not established. As an example, in a multicenter trial, treatment with 20 mg/d of rimonabant, a selective cannabinoid-1 receptor blocker, plus diet for 2 years produced modest but sustained reductions in weight and waist circumference and favorable changes in metabolic risk factors. Counseling appears to be most effective when intensive and combined with behavioral therapy. Maintenance strategies can help preserve weight loss.

In dietary therapy, results from the Women's Health Initiative Dietary Modification Trial showed that a low-fat diet high in vegetables, fruits, and grains produced a modest (2.2 kg, $P < .001$) weight loss that was sustained over prolonged follow-up (1.9 kg, $P < .001$ at 1 year, 0.4 kg, $P = .01$ at 7.5 years). A recent study comparing various diets revealed that Mediterranean (moderate fat, restricted calorie) and low-carbohydrate (non-restricted calorie) diets are effective alternatives to low-fat diets.

Weight loss strategies using dietary, physical activity, or behavioral interventions can produce significant improvements in weight among persons with prediabetes and a significant decrease in diabetes incidence. Multicomponent interventions including very-low-calorie or low-calorie diets hold promise for achieving weight loss in adults with type 2 diabetes mellitus.

Bariatric surgical procedures, eg, vertical banded gastroplasty and Roux-en-Y gastric bypass, are reserved for patients with morbid obesity whose BMI exceeds 40, or for less severely obese patients (with BMIs between 35 and 40) with high-risk comorbid conditions such as life-threatening cardiopulmonary problems (eg, severe sleep apnea, pickwickian syndrome, and obesity-related cardiomyopathy) or severe diabetes mellitus. In selected patients, surgery can produce substantial weight loss (10 to 159 kg) over 1 to 5 years, with rare but sometimes severe complications. Nutritional deficiencies are one complication of bariatric surgical procedures and close monitoring of a patient's metabolic and nutritional status is essential.

Clinicians seem to share a general perception that almost no one succeeds in long-term maintenance of weight loss. However, research demonstrates that approximately 20% of overweight individuals are successful at long-term weight loss (defined as losing 10% of initial body weight and maintaining the loss for 1 year). National Weight Control Registry members who lost an average of 33 kg and maintained the loss for more than 5 years have provided useful information about how to maintain weight loss. Members report engaging in high levels of physical activity (approximately 60 min/d), eating a low-calorie, low-fat diet, eating breakfast regularly, self-monitoring weight, and maintaining a consistent eating pattern from weekdays to weekends. The development and implementation of innovative public health strategies is essential in the fight against obesity. Lessons learned from smoking cessation campaigns may be helpful in the battle against this significant public health concern.

Cancer Prevention

Primary Prevention

Mortality rates of cancer have begun to decrease in the past 2 years; part of this decrease results from reductions in tobacco use, since cigarette smoking is the most important preventable cause of cancer. Preventive health examinations and preventive gynecologic examinations are among the most common reasons for ambulatory care visits, although the use and content of these types of visits remains controversial. Primary prevention of skin cancer consists of restricting exposure to ultraviolet light by wearing appropriate clothing and use of sunscreens. In the past 2 decades, there has been a threefold increase in the incidence of squamous cell carcinoma and a fourfold increase in melanoma in the United States. Persons who engage in regular physical exercise and avoid obesity have lower rates of breast and colon cancer. Prevention of occupationally induced cancers involves minimizing exposure to carcinogenic substances such as asbestos, ionizing radiation, and benzene compounds. Chemoprevention has been widely studied for primary cancer prevention (see above Chemoprevention section and Chapter 39: Cancer). Use of tamoxifen, raloxifene, and aromatase inhibitors for breast cancer prevention is discussed in Chapter 17: Breast Disorders and Chapter 39: Cancer. Hepatitis B vaccination can prevent hepatocellular carcinoma (HCC), and screening and vaccination programs may be cost-effective and useful in preventing HCC in high-risk groups such as Asians and Pacific Islanders. The use of HPV vaccine to prevent cervical cancer is discussed above in the Prevention of

Infectious Disease section.

Screening & Early Detection

Screening has been shown to prevent death from cancers of the breast, colon, and cervix. Current cancer screening recommendations from the American Cancer Society, the Canadian Task Force on Preventive Health Care, and the United States Preventive Services Task Force are shown in Table 1–9.

Table 1–9. Cancer screening recommendations for average-risk adults.

Test	**ACS**[1]	**CTF**[2]	**USPSTF**[3]	
Breast self-examination	An option for women over	Fair evidence that BSE	Insufficient evidence to	

(BSE)	age 20.	*should not* be used.	recommend for or against.	
Clinical breast examination	Every 3 years age 20–40 and annually thereafter.	Good evidence for annual screening women aged 50-69 by clinical examination and mammography.	Insufficient evidence to recommend for or against.	
Mammography	Annually age 40 and older.	Current evidence does not support the recommendation that screening mammography be included in or excluded from the periodic	Recommended every 1–2 years for women aged 40 and over (B).	

		health examination of women aged 40–49.		
Papanicolaou test	Annually beginning within 3 years after first vaginal intercourse or no later than age 21. Screening may be done every 2 years with the liquid-based Pap test.	Annually at age of first intercourse or by age 18; can move to every-2-year screening after two normal results to age 69.	Every 3 years beginning at onset of sexual activity or age 21 (A).	
	After age 30, women with three normal tests may be screened every 2–3 years or every 3 years by Pap test *plus*			

	the HPV DNA test.			
	Women may choose to stop screening after age 70 if they have had three normal (and no abnormal) results within the last 10 years.		Recommends against routinely screening women older than age 65 if they have had adequate recent screening with normal Pap tests and are not otherwise at high risk for cervical cancer (D).	
Annual stool test for occult blood[4] or fecal immunochemical test (FIT)	Screening recommended, with the combination of fecal occult blood	Good evidence for screening every 1–2 years over age 50.	Screening strongly recommended (A), but insufficient evidence to	

	test or fecal immunochemical test (FIT) and sigmoidoscopy preferred over stool test or sigmoidoscopy alone. Double-contrast barium enema and colonoscopy also considered reasonable alternatives.		determine best test.	
Sigmoidoscopy (every 5 years)		Fair evidence for screening over age 50 (insufficient evidence about combining stool test and sigmoidoscopy).		
Double-contrast barium enema (every 5 years)		Not addressed.		
Colonoscopy (every 10 years)		Insufficient evidence for or against use in screening.		
Prostate-specific antigen (PSA) blood test	PSA and DRE should be offered annually to men age 50 and older who have at	Fair evidence *against* including in routine care.	Insufficient evidence to recommend for or against.	
Digital Rectal		Insufficient	Insufficient	

Examination (DRE)	least a 10-year life expectancy. Men at high risk (African American men and men with a strong family history) should begin at age 45. Information should be provided to men about the benefits and risks, and they should be allowed to participate in the decision. Men without a clear preference should be screened.	evidence for or against including in routine care.	evidence to recommend for or against.	

Cancer-related checkup	For people aged 20 or older having periodic health exams, a cancer-related checkup should include counseling and perhaps oral cavity, thyroid, lymph node, or testicular examinations.	Not assessed.	Not assessed.

[2] Canadian Task Force on Preventive Health Care recommendations available at http://www.ctfphc.org.

[3] United States Preventive Services Task Force recommendations available at http://www.ahrq.gov/clinic/uspstfix.htm.

[4] Home test with three samples.

Recommendation A: The USPSTF strongly recommends that clinicians routinely provide the service to eligible patients. (The USPSTF found good evidence that the service improves important health outcomes and concludes that benefits substantially outweigh harms.)

Recommendation B: The USPSTF recommends that clinicians routinely provide the service to eligible patients. (The USPSTF found at least fair evidence that the service improves important health outcomes and concludes that benefits substantially outweigh harms.)

Recommendation D: The USPSTF recommends against routinely providing the service to asymptomatic patients. (The USPSTF found at least fair evidence that the service is ineffective or that harms outweigh benefits.)

The appropriate form and frequency of screening for breast cancer is controversial. A large randomized trial of breast self-examination conducted among factory workers in Shanghai found no benefit. A systematic review performed for the United States Preventive Services Task Force found that mammography was moderately effective in reducing breast cancer mortality for women 40–74 years of age. The absolute benefit was greater for older women, and the risk of false-positive results was high for all women. Digital mammography is more sensitive in women with dense breasts and younger women; however, studies exploring outcomes are lacking. Several organizations, including the American Cancer Society and the National Cancer Institute, recommend routine mammography screening, and changes in screening guidelines appear to impact women's beliefs about how frequently they should obtain screening. Although delays to following up an abnormal mammogram exist, the use of patient navigation programs to reduce such delays appears beneficial, especially among poor and minority populations. The use of MRI is not currently recommended for general screening, although the American Cancer Society does recommend screening MRI for women at high risk (20–25%), including those with a strong family history of breast or ovarian cancer. A recent systematic review reported that screening with both MRI and mammography might be superior to mammography alone in ruling out cancerous lesions in women with an inherited predisposition to breast cancer.

All current recommendations call for cervical and colorectal cancer screening. Prostate cancer screening, however, is controversial, as no completed studies have answered the question whether early detection and treatment after screen detection produce sufficient benefits to outweigh harms of treatment. A 2008 USPSTF review of current evidence on benefits and harm of screening asymptomatic men for prostate cancer with prostate-specific antigen (PSA) testing revealed that PSA screening is associated with increased psychological harm with uncertain potential benefits. Providers and patients are advised to discuss how to proceed in light of this uncertainty. Whether early detection through screening and subsequent treatment alters the natural course of the disease remains to be seen. There are still no data on the morbidity and mortality benefits of screening. Unlike the American College of Physicians, the American Cancer Society recommends that providers offer annual PSA testing for men over age 50. Screening is not recommended by any group for men who have estimated life expectancies of less than 10 years. Decision aids have been developed to help men weigh the arguments for and against PSA screening.

Annual or biennial fecal occult blood testing reduces mortality from colorectal cancer by 16–33%. The risk of death from colon cancer among patients undergoing at least one sigmoidoscopic examination is reduced by 60–80% compared with that among those not having sigmoidoscopy. Colonoscopy has also been advocated as a screening examination. It is more accurate than flexible sigmoidoscopy for detecting cancer and polyps, but its value in reducing colon cancer mortality has not been studied directly. Recent studies have shown that CT colography (virtual colonoscopy) is also able to detect cancers and polyps with reasonable accuracy.

Screening for cervical cancer with a Papanicolaou smear is indicated in sexually active adolescents and in adult women every 1–3 years. Screening for vaginal cancer with a Papanicolaou smear is not indicated in women who have undergone hysterectomies for benign disease with removal of the cervix—except in diethylstilbestrol (DES)-exposed women (see Chapter 18: Gynecologic Disorders). Women over age 70 who have had normal results on three or more previous Papanicolaou smears may elect to stop screening.

Screening for lung cancer with spiral CT can detect early stage disease; however, its efficacy in reducing lung cancer mortality has not been evaluated in a randomized trial, although a recent study of survival in asymptomatic patients at risk for lung cancer who were screened annually with spiral CT revealed that such screening detected lung cancer at a curable stage.

Prevention of Injuries & Violence

Injuries remain the most important cause of loss of potential years of life before age 65. Homicide and motor vehicle accidents are a major cause of injury-related deaths among young adults, and accidental falls are the most common cause of injury-related death in the elderly. Other causes of injury-related deaths include suicide and accidental exposure to smoke, fire, and flames.

Although there has been a steady decline in motor vehicle accident deaths per miles driven, road traffic injuries remain the tenth leading cause of death and the ninth leading cause of the burden of disease. Although seat belt use protects against serious injury and death in motor vehicle accidents, at least one-fourth of adults and one-third of teenagers do not use seat belts routinely. Air bags are protective for adults but not for small children.

Each year in the United States, more than 500,000 people are nonfatally injured while riding bicycles. The rate of helmet use by bicyclists and motorcyclists is significantly increased in states with helmet laws. Young men appear most likely to resist wearing helmets. Clinicians should try to educate their patients about seat belts, safety helmets, the risks of using cellular telephones while driving, drinking and driving—or using other intoxicants or long-acting benzodiazepines and then driving—and the risks of having guns in the home.

Long-term alcohol abuse adversely affects outcome from trauma and increases the risk of readmission for new trauma. Alcohol and illicit drug use are associated with an increased risk of violent death. There is a causal link between alcohol intoxication and injury due to assault. Harm reduction can be achieved through practical measures, such as using plastic glasses and bottles in licensed premises; controlling prices of drinks; and targeted policing based on police, accident, and emergency data.

Males aged 16–35 are at especially high risk for serious injury and death from accidents and violence, with blacks and Latinos at greatest risk. For 16- and 17-year-old drivers, the risk of fatal crashes increases with the number of passengers. Deaths from firearms have reached epidemic levels in the United States and will soon surpass the number of deaths from motor vehicle accidents. Having a gun in the home increases the likelihood of homicide nearly threefold and of suicide fivefold. In 2002, an estimated 877,000 individuals successfully committed suicide. Educating physicians to recognize and treat depression as well as restricting access to lethal methods have been found to reduce suicide rates.

In elderly patients, the risk of hip fracture when falling can be reduced by as much as 80% by wearing hip protectors, but only about half of patients use them regularly. Oral vitamin D supplementation with 700–800 international units/d appears to reduce the risk of hip and other nonvertebral fractures in both ambulatory and institutionalized elderly persons, but 400 international units/d is not sufficient for fracture prevention.

Finally, clinicians have a critical role in detection, prevention, and management of physical or sexual abuse—in particular, routine assessment of women for risk of domestic violence. In a trial, the 12-month prevalence of intimate partner violence ranged from 4% to 18% depending on the screening method, instrument, and health care setting. Rates of current domestic violence on exit questionnaire were 21% in suburban emergency department and 26% in urban emergency department settings. Inclusion of a single question about domestic violence in the medical history—"At any time, has a partner ever hit you, kicked you, or otherwise physically hurt you?"—can increase identification of this common problem. Another screen consists of three questions: (1) "Have you ever been hit, kicked, punched, or otherwise hurt by someone within the past year? If so, by whom?" (2) "Do you feel safe in your current relationship?" (3) "Is there a partner from a previous relationship who is making you feel unsafe now?" Women seem to prefer written, self-completed screening questionnaires to face-to-face questioning. Alternatively, computer prompts to clinicians may serve as useful reminders to inquiry. Assessment for abuse and offering of referrals to community resources creates potential to interrupt and prevent recurrence of domestic violence and associated trauma. Screening patients in emergency departments for intimate partner violence appears to have no adverse effects related to screening and may lead to increased patient contact with community resources.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Physical and psychological abuse, exploitation, and neglect of older adults are serious underrecognized problems. Clues to elder mistreatment include the patient's appearance, recurrent urgent-care visits, missed appointments, suspicious physical findings, and implausible explanations for injuries.

Prevention of Substance Abuse: Alcohol & Illicit Drugs

Substance abuse is a major public health problem in the United States. The lifetime prevalence of alcohol abuse is approximately 18%, whereas the lifetime prevalence of alcohol dependence is near 13%. Rates appear to be higher in men, whites, and younger and unmarried individuals. Approximately two-thirds of high school seniors are regular users of alcohol. Alcohol dependence often coexists with other substance disorders as well as with mood, anxiety, and personality disorders. Underdiagnosis and treatment of alcohol abuse is substantial, both because of patient denial and lack of detection of clinical clues. Treatment rates for alcohol dependence have slightly declined over the last several years. Only a quarter of alcohol-dependent patients have ever been treated.

As with cigarette use, clinician identification and counseling about alcoholism may improve the chances of recovery. About 10% of all adults seen in medical practices are problem drinkers. An estimated 15–30% of hospitalized patients have problems with alcohol abuse or dependence, but the connection between patients' presenting complaints and their alcohol abuse is often missed. The CAGE test (see Table 1–10) is both sensitive and specific for chronic alcoholism. However, it is less sensitive in detecting heavy or binge drinking in elderly patients and has been criticized for being less applicable to minority groups or to women. Others recommend asking three questions: (1) How many days per week do you drink (frequency)? (2) On a day when you drink alcohol, how many drinks do you have in one day (quantity)? (3) On how many occasions in the last month did you drink more than five drinks (binge drinking)? The Alcohol Use Disorder Identification Test (AUDIT) consists of questions on the quantity and frequency of alcohol consumption, on alcohol dependence symptoms, and on alcohol-related problems (Table 1–10). The AUDIT questionnaire is a cost-effective and efficient diagnostic tool for routine screening of alcohol use disorders in primary care settings. Choice of therapy remains controversial. However, use of screening procedures and brief intervention methods (Table 1–11; see Chapter 25: Psychiatric Disorders) can produce a 10–30% reduction in long-term alcohol use and alcohol-related problems. However, brief advice and counseling without regular follow-up and reinforcement cannot sustain significant long-term reductions in unhealthy drinking behaviors.

Put Prevention Into Practice. U.S. Government Printing Office, 1994.

Several pharmacologic agents are effective in reducing alcohol consumption. In acute alcohol detoxification, standard treatment regimens use long-acting benzodiazepines, the preferred medications for alcohol detoxification, because they can be given on a fixed schedule or through "front-loading" or "symptom-triggered" regimens. Adjuvant sympatholytic medications can be used to treat hyperadrenergic symptoms that persist despite adequate sedation. Three drugs are FDA approved for treatment of alcohol dependence—disulfiram, naltrexone, and acamprosate. Disulfiram, an aversive agent, has significant adverse effects and consequently, compliance difficulties have resulted in no clear evidence that it increases abstinence rates, decreases relapse rates, or reduces cravings. Persons who receive short-term treatment with naltrexone have a lower chance of alcoholism relapse. Compared with placebo, naltrexone can lower the risk of treatment withdrawal in alcohol-dependent patients. Compared with placebo, long-acting intramuscular formulation of naltrexone has been found to be well-tolerated and to reduce drinking significantly among treatment-seeking alcoholics over a 6-month period. In a randomized, controlled trial, patients receiving medical management with naltrexone, a combined behavioral intervention, or both fared better on drinking outcomes, whereas acamprosate showed no evidence of efficacy with or without combined behavioral intervention. Topiramate, although not yet FDA approved for this indication, is a promising treatment for alcohol dependence. In a recent randomized control trial, topiramate was more effective than placebo at reducing the percentage of heavy drinking days from baseline to week 14.

Use of illegal drugs—including cocaine, methamphetamine, and so-called "designer drugs"—either sporadically or episodically remains an important problem. Lifetime prevalence of drug abuse is approximately 8% and is generally greater among men, young and unmarried individuals, Native Americans, and those of lower socioeconomic status. As with alcohol, drug abuse disorders often coexist with personality, anxiety, and other substance abuse disorders.

Abuse of anabolic-androgenic steroids has been associated with use of other illicit drugs, alcohol, and cigarettes and with violence and criminal behavior. As with alcohol abuse, the lifetime treatment rate for drug abuse is low (8%). The recognition of drug abuse presents special problems and requires that the clinician actively consider the diagnosis. Clinical aspects of substance abuse are discussed in Chapter 25: Psychiatric Disorders.

Currently, evidence does not support the use of carbamazepine, disulfiram, mazindol, phenytoin, nimodipine, lithium, antidepressants, or dopamine agonists in the treatment of cocaine dependence. In a methadone maintenance population, the combination of contingency management with bupropion is more effective than bupropion alone for the treatment of cocaine addiction.

Buprenorphine has potential as a medication to ameliorate the symptoms and signs of withdrawal from opioids and has been shown to be effective in reducing concomitant cocaine and opiate abuse. A stepped treatment program for heroin dependence using buprenorphine/naloxone, escalated to methadone if needed, has been shown to be equally effective as methadone maintenance therapy. Cessation of methadone maintenance is possible using buprenorphine by transfer from methadone to buprenorphine and subsequent buprenorphine reductions. Evidence does not support the use of naltrexone in maintenance treatment of opioid addiction. Rapid opioid detoxification with opioid antagonist induction using general anesthesia has emerged as an approach to treat opioid dependence. However, a randomized comparison of buprenorphine-assisted rapid opioid detoxification with naltrexone induction and clonidine-assisted opioid detoxification with delayed naltrexone induction found no significant differences in rates of completion of inpatient detoxification, treatment retention, or proportions of opioid-positive urine specimens, and the anesthesia procedure was associated with more potentially life-threatening adverse events. Finally, cognitive behavior therapy, contingency management, couples and family therapy, and other types of behavioral treatment have been shown to be effective interventions for drug addiction.

Common Symptoms: Introduction

New or unexplained symptoms account for about half of all office visits; the remainder of visits are for ongoing care of established medical conditions. Evidence-based symptom evaluation combines knowledge of a symptom's clinical epidemiology with disease candidates according to Bayesian principles, such that the likelihood of a specific disease is a function of patient demographics, comorbidities, and clinical features. This knowledge can help support decisions about further testing or treatment or whether to perform additional testing before treatment, or to treat without further testing.

In addition to epidemiologic factors, biological, psychological, social, and cultural factors affect how patients process, filter, and interpret symptoms. Patients vary in deciding when symptoms are sufficiently bothersome or worrisome to cause them to seek medical attention, and in what they expect from the office visit.

Many symptoms defy diagnosis. If symptom relief is not easily achieved, treatment of these patients becomes challenging. The shift toward evidence-based principles of medicine, which encourage narrow study questions in homogeneous study populations, inadvertently ignores syndromes that are not readily explained by current biomedical models of disease. Conversely, even when the cause of a disease is known, host and environmental factors can influence the symptoms that are manifested. For example, in 1967, Evans proposed five "realities" that reflect the conundrum clinicians face when associating an acute respiratory syndrome with an etiologic pathogen: (1) The same clinical syndrome may be produced by a variety of infectious pathogens; (2) the same pathogen may produce a variety of syndromes; (3) the most likely cause of a syndrome may vary by patient age, year, geography, and setting; (4) diagnosis of the pathogen is frequently impossible on the basis of clinical findings alone; and (5) the causes of a large proportion of infectious disease syndromes are still unknown.

Cough

Essential Inquiries

- Age.
- Duration of cough.
- Dyspnea (at rest or with exertion).
- Tobacco use history.
- Vital signs (heart rate, respiratory rate, body temperature).
- Chest examination.
- Chest radiography when unexplained cough lasts more than 3–6 weeks.

General Considerations

Cough adversely affects personal and work-related interactions, disrupts sleep, and often causes discomfort of the throat and chest wall. Most people seeking medical attention for acute cough desire symptom relief; few are worried about serious illness. Cough results from stimulation of mechanical or chemical afferent nerve receptors in the bronchial tree. Effective cough depends on an intact afferent–efferent reflex arc, adequate expiratory and chest wall muscle strength, and normal mucociliary production and clearance.

Clinical Findings

Symptoms

Distinguishing acute (< 3 weeks), persistent (> 3 weeks), and chronic (> 8 weeks) cough illness syndromes is a useful first step in evaluation. In healthy adults, most acute cough syndromes are due to viral respiratory tract infections. Postinfectious cough lasting 3–8 weeks has also been referred to as subacute cough to distinguish this common, distinct clinical entity from acute and chronic cough. Additional features of infection such as fever, nasal congestion, and sore throat help confirm the diagnosis. Dyspnea (at rest or with exertion) may reflect a more serious condition, and further evaluation should include assessment of oxygenation (pulse oximetry or arterial blood gas measurement), airflow (peak flow or spirometry), and pulmonary parenchymal disease (chest radiography). The timing and character of the cough have not been found to be very useful in establishing the cause of acute cough syndromes, although cough-variant asthma should be considered in adults with prominent nocturnal cough, and persistent cough with phlegm increases the patient's likelihood of chronic obstructive pulmonary disease (COPD). Uncommon causes of acute cough illness should be suspected in those with heart disease (congestive heart failure [CHF]) or hay fever (allergic rhinitis) and those with environmental risk factors (such as farm workers).

Cough due to acute respiratory tract infection resolves within 3 weeks in the vast majority of patients (over 90%). Pertussis infection should be considered in previously immunized adults with persistent or severe cough lasting more than 2–3 weeks and approaches a prevalence of 20% when cough has persisted beyond 3 weeks.

When angiotensin-converting enzyme (ACE) inhibitor therapy, acute respiratory tract infection, and chest radiograph abnormalities are absent, up to 90% of cases of persistent cough are due to or exacerbated by postnasal drip, asthma, or gastroesophageal reflux disease (GERD). A history of nasal or sinus congestion, wheezing, or heartburn should direct subsequent evaluation and treatment, though these conditions frequently cause persistent cough in the absence of typical symptoms. Bronchogenic carcinoma is suspected when cough is accompanied by unexplained weight loss and fevers with night sweats, particularly in persons with significant tobacco or occupational exposures. Persistent cough accompanied by excessive mucus secretions increases the likelihood of COPD, particularly among smokers, or bronchiectasis in a patient with a history of recurrent or complicated pneumonia; chest radiographs are helpful in diagnosis. Dyspnea at rest or with exertion is not commonly reported among patients with persistent cough. The report of dyspnea requires assessment for other evidence of chronic lung disease, CHF, or anemia.

Physical Examination

Examination can direct subsequent diagnostic testing for acute and persistent cough. Pneumonia is suspected when acute cough is accompanied by vital sign abnormalities (tachycardia, tachypnea, fever). Findings suggestive of airspace consolidation (rales, decreased breath sounds, fremitus, egophony) are significant predictors of community-acquired pneumonia but are present in a small number of cases. Purulent sputum is associated with bacterial infections in patients with structural lung disease (eg, COPD, cystic fibrosis), but it is a poor predictor of pneumonia in the otherwise healthy adult. Wheezing and rhonchi are frequent findings in adults with acute bronchitis and do not represent adult-onset asthma in most cases.

Physical examination of adults with persistent cough should look for evidence of chronic sinusitis, contributing to postnasal drip syndrome or asthma. Chest and cardiac signs may help distinguish COPD from CHF. In patients with cough and dyspnea, a normal match test (ability to blow out a match from 25 cm away) and maximum laryngeal height > 4 cm (measured from the sternal notch to the cricoid cartilage at end expiration) substantially decrease the likelihood of COPD. Similarly, normal jugular venous pressure and negative hepatojugular reflux decrease the likelihood of biventricular CHF.

Diagnostic Studies

Acute Cough

Chest radiography should be considered for any adult with acute cough who shows abnormal vital signs or in whom the chest examination is suggestive of pneumonia. The relationship between specific clinical findings and the probability of pneumonia is shown in Figure 2–1: illustration. In patients with dyspnea, pulse oximetry and peak flow help exclude hypoxemia or obstructive airway disease. However, a normal pulse oximetry value (eg, > 93%) does not rule out a significant alveolar–arterial (A–a) gradient when patients have effective respiratory compensation. During documented influenza outbreaks, the positive predictive value of clinical diagnosis of influenza approaches 70% and usually obviates the usefulness of rapid diagnostic tests.

Figure 2–1

Revised pneumonia probabilities based on history and physical examination findings. (Reproduced, with permission, from Metlay JP et al. Testing strategies in the initial management of patients with community-acquired pneumonia. Ann Intern Med. 2003 Jan 21;138(2):109–18.)

Persistent and chronic cough

Chest radiography is indicated when ACE inhibitor therapy–related and postinfectious cough are excluded by history or further diagnostic testing. If pertussis infection is suspected, testing should be performed using polymerase chain reaction on a nasopharyngeal swab or nasal wash specimen—keeping in mind that the ability to detect pertussis decreases as the duration of cough increases. When the chest film is normal, postnasal drip, asthma, and GERD are the most likely causes. The presence of typical symptoms of these conditions directs further evaluation or empiric therapy, though typical symptoms are often absent. Definitive procedures for determining the presence of each are available (Table 2–1). However, empiric treatment with a maximum-strength regimen for postnasal drip, asthma, or GERD for 2–4 weeks is one recommended approach since documenting the presence of postnasal drip, asthma, and GERD does not mean they are the cause of the cough illness. Other alternative approaches include the following: first, identify patients who have corticosteroid-responsive cough by examining induced sputum for increased eosinophil counts (> 3%); second, measure increased exhaled nitric oxide levels; or third, start an empiric trial of prednisolone, 30 mg daily for 2 weeks. Spirometry may help identify large airway obstruction in patients who have persistent cough and wheezing and who are not responding to asthma treatment. When empiric treatment trials are not helpful, additional evaluation with pH manometry, endoscopy, barium swallow, sinus CT or high-resolution chest CT may identify the cause.

Table 2–1. Empiric treatments or tests for persistent cough.

Suspected Condition	**Step 1 (Empiric Therapy)**	**Step 2 (Diagnostic Testing)**
Postnasal drip	Therapy for allergy or chronic sinusitis	ENT referral; sinus CT scan
Asthma	$_2$-Agonist	Spirometry; consider methacholine challenge if normal
GERD	Proton pump inhibitors	Esophageal pH monitoring

ENT, ear, nose, and throat; GERD, gastroesophageal reflux disease.

Differential Diagnosis

Acute Cough

Acute cough may be a symptom of acute respiratory tract infection, asthma, allergic rhinitis, and CHF, as well as a myriad of other less common causes.

Persistent and Chronic Cough

Causes of persistent cough include environmental exposures (cigarette smoke, air pollution), pertussis infection, postnasal drip syndrome (or upper airway cough syndrome), asthma (including cough-variant asthma), GERD, COPD, bronchiectasis, eosinophilic bronchitis, tuberculosis or other chronic infection, interstitial lung disease, and bronchogenic carcinoma. Persistent cough may also be psychogenic.

Treatment

Acute Cough

Treatment of acute cough should target the underlying etiology of the illness, the cough reflex itself, and any additional factors that exacerbate the cough. When influenza is diagnosed, treatment with amantadine, rimantadine, oseltamivir, or zanamivir is equally effective (1 less day of illness) when initiated within 30–48 hours of illness onset. In the setting of *Chlamydia* or

Mycoplasma-documented infection or outbreaks, first-line antibiotics include erythromycin, 250 mg orally four times daily for 7 days, or doxycycline, 100 mg orally twice daily for 7 days. In patients diagnosed with acute bronchitis, inhaled $_2$-agonist therapy reduces severity and duration of cough in some patients. Evidence supports a modest benefit of dextromethorphan, but not codeine, on cough severity in adults with cough due to acute respiratory tract infections. Treatment of postnasal drip (with antihistamines, decongestants, or nasal corticosteroids) or GERD (with H_2-blockers or proton-pump inhibitors), when accompanying acute cough illness, can also be helpful. There is good evidence that vitamin C and echinacea are not effective in reducing the severity of acute cough illness after it develops; however, evidence does support vitamin C (at least 1 g daily) for prevention of colds among persons with major physical stressors (eg, post-marathon) or malnutrition.

Persistent and Chronic Cough

Evaluation and management of persistent cough often requires multiple visits and therapeutic trials, which frequently lead to frustration, anger, and anxiety. When pertussis infection is suspected or confirmed, treatment with macrolide antibiotics is appropriate to reduce shedding and transmission of the organism. When pertussis infection has lasted more than 7–10 days, antibiotic treatment does not affect the duration of cough, which can last up to 6 months. There is no evidence to guide how long treatment for persistent cough due to postnasal drip, asthma, or GERD should be continued.

When to Refer

- Failure to control persistent or chronic cough following empiric treatment trials. The small percentage of patients with idiopathic persistent cough should be managed in consultation with an otolaryngologist or a pulmonologist; treatment options include nebulized lidocaine therapy and morphine sulfate, 5–10 mg orally twice daily.
- Patients with recurrent symptoms should be referred to an otolaryngologist or a pulmonologist.

When to Admit

- Patient at high risk for tuberculosis for whom compliance with respiratory precautions is uncertain.
- Need for urgent bronchoscopy, such as suspected foreign body.
- Smoke or toxic fume inhalational injury.
- Intractable cough treatment, when cough impairs gas exchange or in patients at high risk for barotraumas (eg, recent pneumothorax).

Dyspnea

Essential Inquiries

- Fever.
- Cough.

- Chest pain.
- Vital sign measurements; pulse oximetry.
- Cardiac and chest examination.
- Chest radiography.
- Arterial blood gas measurement.

General Considerations

Dyspnea is a subjective experience or *perception* of uncomfortable breathing. However, the relationship between level of dyspnea and the severity of underlying disease varies widely across individuals. Dyspnea can result from conditions that increase the mechanical effort of breathing (eg, COPD, restrictive lung disease, respiratory muscle weakness), from conditions that produce compensatory tachypnea (eg, hypoxemia or acidosis), or from psychogenic origins. Rate of onset, previous dyspnea, medications, comorbidities, psychological profile, and severity of underlying disorder play a role in how and when persons present with dyspnea. In patients with established COPD, the patient-reported severity of dyspnea is superior to forced expiratory volume in 1 second (FEV_1) in predicting quality of life and 5-year mortality.

Clinical Findings

Symptoms

The duration, severity, and periodicity of dyspnea influence the tempo of the clinical evaluation. Rapid onset, severe dyspnea in the absence of other clinical features should raise concern for pneumothorax, pulmonary embolism, or increased left ventricular end-diastolic pressure (LVEDP). Spontaneous pneumothorax is usually accompanied by chest pain and occurs most often in thin, young males, or in those with underlying lung disease. Pulmonary embolism should always be suspected when a patient reports a recent history (previous 4 weeks) of prolonged immobilization, estrogen therapy, or other risk factors for deep venous thrombosis (DVT) (eg, previous history of thromboembolism, cancer, obesity) and when the cause of dyspnea is not apparent. Silent myocardial infarction, which occurs more frequently in diabetic persons and women, can result in acute heart failure and dyspnea.

Accompanying symptoms provide important clues to various etiologies of dyspnea. When cough and fever are present, pulmonary disease (particularly infections) is the primary concern, although myocarditis, pericarditis, and septic emboli can also present in this manner. Chest pain should be further characterized as acute or chronic, pleuritic or exertional. Although acute pleuritic chest pain is the rule in acute pericarditis and pneumothorax, most patients with pleuritic chest pain in the outpatient clinic have pleurisy due to acute viral respiratory tract infection. Periodic chest pain that precedes the onset of dyspnea is suspicious for myocardial ischemia as well as pulmonary embolism. When associated with wheezing, most cases of dyspnea are due to acute bronchitis; however, when acute bronchitis seems unlikely, the clinician should also consider new-onset asthma, foreign body, and vocal cord dysfunction.

When a patient reports prominent dyspnea with mild or no accompanying features, consider noncardiopulmonary causes of impaired oxygen delivery (anemia, methemoglobinemia, cyanide ingestion, carbon monoxide), metabolic acidosis due to a variety of conditions, panic disorder, and chronic pulmonary embolism.

Physical Examination

A focused physical examination should include evaluation of the head and neck, chest, heart, and lower extremities. Visual inspection of the patient's respiratory pattern can suggest obstructive airway disease (pursed-lip breathing, use of extra respiratory muscles, barrel-shaped chest), pneumothorax (asymmetric excursion), or metabolic acidosis (Kussmaul respirations). Patients with impending upper airway obstruction (eg, epiglottitis, foreign body), or severe asthma exacerbation, sometimes assume a tripod position. Focal wheezing raises the suspicion for a foreign body or other bronchial obstruction. Maximum laryngeal height (the distance between the top of the thyroid cartilage and the suprasternal notch at end expiration) is a measure of hyperinflation. Obstructive airway disease is virtually nonexistent when a nonsmoking patient younger than 45 years has a maximum laryngeal height 4 cm (Table 2–2).

Table 2–2. Clinical findings suggesting obstructive airways disease.

	Adjusted Likelihood Ratios	
	Factor Present	**Factor Absent**
> 40 pack-years smoking	11.6	0.9
Age 45 years	1.4	0.5
Maximum laryngeal height 4 cm	3.6	0.7
All three factors	58.5	0.3

Reproduced, with permission, from Straus SE et al. The accuracy of patient history, wheezing, and laryngeal measurements in diagnosing obstructive airway disease. CARE-COAD1 Group. Clinical Assessment of the Reliability of the Examination—Chronic Obstructive Airways Disease. JAMA. 2000 Apr 12;283(14):1853–7.

A systematic review has identified several clinical predictors of increased LVEDP useful in the evaluation of dyspneic patients with no prior history of CHF (Table 2–3). When none is present, there is a very low probability (< 10%) of increased LVEDP, and when two or more are present, there is a very high probability (> 90%) of increased LVEDP.

Table 2–3. Clinical findings suggesting increased left ventricular end-diastolic pressure.
Tachycardia
Systolic hypotension
Jugular venous distention (> 5–7 cm H_2O)[1]
Hepatojugular reflux (> 1 cm)[2]
Crackles, especially bibasilar
Third heart sound[3]
Lower extremity edema
Radiographic pulmonary vascular redistribution or cardiomegaly[1]

[1] These findings are particularly helpful.

[2] Proper abdominal compression for evaluating hepatojugular reflux requires > 30 seconds of sustained right upper quadrant abdominal compression.

[3] Cardiac auscultation of the patient at 45-degree angle in left lateral decubitus position doubles the detection rate of third heart sounds.

Modified, with permission, from Badgett RG et al. Can the clinical examination diagnose left-sided heart failure in adults? JAMA. 1997 Jun 4;277(21):1712–9.

Diagnostic Studies

Causes of dyspnea that can be managed without chest radiography are few: ingestions causing lactic acidosis, methemoglobinemia, and carbon monoxide poisoning. The diagnosis of pneumonia should be confirmed by chest radiography in most patients. When COPD exacerbation is severe enough to require hospitalization, results of chest radiography can influence management decisions in up to 20% of patients. Chest radiography is fairly sensitive and specific for new-onset CHF (represented by redistribution of pulmonary venous circulation) and can help guide treatment decisions in patients with dyspnea secondary to cardiac disease. End-expiratory chest radiography enhances detection of a small pneumothorax.

A *normal* chest radiograph has substantial diagnostic value. When there is no physical examination evidence of COPD or CHF and the chest radiograph is normal, the major remaining causes of dyspnea include pulmonary embolism, upper airway obstruction, foreign body, anemia, and metabolic acidosis. If a patient has tachycardia and hypoxemia but a normal chest radiograph and electrocardiogram (ECG), then further tests to exclude pulmonary emboli are warranted (see Chapter 9: Pulmonary Disorders), provided blood tests exclude significant anemia or metabolic acidosis. High-resolution chest CT is particularly useful in the evaluation of pulmonary embolism and has the added benefit of providing information about interstitial and alveolar lung disease.

Serum or whole blood brain natriuretic peptide (BNP) testing can be useful in distinguishing cardiac from noncardiac causes of dyspnea in the emergency department, since elevated BNP levels are both sensitive and specific for increased LVEDP in symptomatic persons.

Persistent uncertainty following clinical examination and routine diagnostic testing warrants arterial blood gas measurement. With two notable exceptions (carbon monoxide poisoning and cyanide toxicity), arterial blood gas measurement distinguishes increased mechanical effort causes of dyspnea (respiratory acidosis with or without hypoxemia) from compensatory tachypnea (respiratory alkalosis with or without hypoxemia or metabolic acidosis) from psychogenic dyspnea (respiratory alkalosis). Carbon monoxide and cyanide impair oxygen delivery with minimal alterations in PO_2; percent carboxyhemoglobin identifies carbon monoxide toxicity. Cyanide poisoning should be considered in a patient with profound lactic acidosis following a theater fire. Suspected carbon monoxide poisoning or methemoglobinemia can also be confirmed with venous carboxyhemoglobin or methemoglobin levels.

Because arterial blood gas testing is impractical in most outpatient settings, **pulse oximetry** has assumed a central role in the office evaluation of dyspnea. Oxygen saturation values above 96% almost always correspond with a Po_2 > 70 mm Hg, and values less than 94% almost always represent clinically significant hypoxemia. Important exceptions to this rule include carbon monoxide toxicity, which leads to a normal oxygen saturation (due to the similar wavelengths of oxyhemoglobin and carboxyhemoglobin), and methemoglobinemia, which results in an oxygen saturation of about 85% that fails to increase with supplemental oxygen. A normal or mildly abnormal oxygen saturation (< 90%) in a delirious or obtunded patient with obstructive lung disease warrants immediate measurement of arterial blood gases to exclude hypercapnia and the need for intubation. When pulse oximetry yields equivocal results, assessment of desaturation with ambulation (eg, a brisk walk around the clinic) can be a useful finding (eg, when *Pneumocystis jiroveci* pneumonia is suspected).

Episodic dyspnea can be challenging if an evaluation cannot be performed during symptoms. Life-threatening causes include recurrent pulmonary embolism, myocardial ischemia, and reactive airway disease. When associated with audible wheezing, vocal cord dysfunction should be considered, particularly in a young woman who does not respond to asthma therapy. Spirometry is very helpful in further classifying patients with obstructive airway disease but is rarely needed in the initial or emergent evaluation of patients with acute dyspnea.

Differential Diagnosis

Acute dyspnea, particularly as the chief complaint, demands urgent evaluation. Urgent and emergent conditions causing acute dyspnea include pneumonia, COPD, asthma, pneumothorax, pulmonary embolism, cardiac disease (eg, CHF, acute myocardial infarction, valvular dysfunction, arrhythmia, cardiac shunt), metabolic acidosis, cyanide toxicity, methemoglobinemia, and carbon monoxide poisoning.

Treatment

The treatment of urgent or emergent causes of dyspnea should aim to relieve the underlying cause. Pending diagnosis, patients with hypoxemia should be immediately provided supplemental oxygen unless significant hypercapnia is present or strongly suspected pending arterial blood gas measurement. Dyspnea frequently occurs in patients nearing the end of life; whereas opioid therapy can provide substantial relief independent of the severity of hypoxemia, oxygen therapy appears to be most beneficial to patients with significant hypoxemia (see Chapter 5: Palliative Care & Pain Management). In patients with severe COPD, oxygen therapy improves mortality and exercise performance. Pulmonary rehabilitation programs are another therapeutic option for patients with moderate to severe COPD or interstitial pulmonary fibrosis.

When to Refer

- Patients with advanced COPD should be referred to a pulmonologist, and patients with CHF or valvular heart disease should be referred to a cardiologist following acute stabilization.
- Cyanide toxicity should be managed in conjunction with a toxicologist.

When to Admit

- Impaired gas exchange from any cause or high risk of pulmonary embolism pending definitive diagnosis.
- Suspected cyanide poisoning.

Hemoptysis

Essential Inquiries

- Smoking history.
- Fever, cough, and other symptoms of lower respiratory tract infection.
- Nasopharyngeal or gastrointestinal bleeding.
- Chest radiography and complete blood count.

General Considerations

Hemoptysis is the expectoration of blood that originates below the vocal cords. It is commonly classified as trivial, mild, or massive—the latter defined as more than 200–

600 mL (about 1–2 cups) in 24 hours. The dividing lines are arbitrary, since the amount of blood is rarely quantified with precision. Massive hemoptysis can be usefully defined as any amount that is hemodynamically significant or threatens ventilation, in which case the initial management goal is not diagnostic but therapeutic.

The lungs are supplied with a dual circulation. The pulmonary arteries arise from the right ventricle to supply the pulmonary parenchyma in a low-pressure circuit. The bronchial arteries arise from the aorta or intercostal arteries and carry blood under systemic pressure to the airways, blood vessels, hila, and visceral pleura. Although the bronchial circulation represents only 1–2% of total pulmonary blood flow, it can increase dramatically under conditions of chronic inflammation—eg, chronic bronchiectasis—and is frequently the source of hemoptysis.

The causes of hemoptysis can be classified anatomically. Blood may arise from the airways in COPD, bronchiectasis, and bronchogenic carcinoma; from the pulmonary vasculature in left ventricular failure, mitral stenosis, pulmonary embolism, and arteriovenous malformations; or from the pulmonary parenchyma in pneumonia, inhalation of crack cocaine, or autoimmune diseases (such as Goodpasture disease or Wegener granulomatosis). Diffuse alveolar hemorrhage is due to small vessel bleeding usually caused by autoimmune or hematologic disorders and results in alveolar infiltrates on chest radiography. Most cases of hemoptysis presenting in the outpatient setting are due to infection (eg, acute or chronic bronchitis, pneumonia, tuberculosis). Hemoptysis due to lung cancer increases with age, accounting for up to 20% of cases among the elderly. Less commonly (< 10% of cases), pulmonary venous hypertension (eg, mitral stenosis, pulmonary embolism) causes hemoptysis. Most cases of hemoptysis that have no visible cause on CT scan or bronchoscopy will resolve within 6 months without treatment, with the notable exception of patients at high risk for lung cancer (smokers older than 40 years). Iatrogenic hemorrhage may follow transbronchial lung biopsies, anticoagulation, or pulmonary artery rupture due to distal placement of a balloon-tipped catheter. No cause is identified in up to 15–30% of cases.

Clinical Findings

Symptoms

Blood-tinged sputum in the setting of an upper respiratory tract infection in an otherwise healthy, young (age < 40 years) nonsmoker does not warrant an extensive diagnostic evaluation if the hemoptysis subsides with resolution of the infection. However, hemoptysis is frequently a sign of serious disease, especially in patients with a high prior probability of underlying pulmonary pathology. One should not distinguish between blood-streaked sputum and cough productive of blood alone with regard to the evaluation plan. The goal of the history is to identify patients at risk for one of the disorders listed above. Pertinent features include past or current tobacco use, duration of symptoms, and the presence of respiratory infection. Nonpulmonary sources of hemorrhage—from the nose or the gastrointestinal tract—should also be excluded.

Physical Examination

Elevated pulse, hypotension, and decreased oxygen saturation suggest large volume hemorrhage that warrants emergent evaluation and stabilization. The nares and oropharynx should be carefully inspected to identify a potential upper airway source of bleeding. Chest and cardiac examination may reveal evidence of CHF, or mitral stenosis.

Diagnostic Studies

Diagnostic evaluation should include a chest radiograph and complete blood count. Kidney function tests, urinalysis, and coagulation studies are appropriate in specific circumstances. Hematuria that accompanies hemoptysis may be a clue to Goodpasture syndrome or vasculitis. Flexible bronchoscopy reveals endobronchial cancer in 3–6% of patients with hemoptysis who have a normal (non-lateralizing) chest radiograph. Nearly all of these patients are smokers over the age of 40, and most will have had symptoms for more than 1 week. Bronchoscopy is indicated in such patients. High-resolution chest CT scan complements bronchoscopy and should be strongly considered in patients with normal chest radiograph and low risk for malignancy. It can visualize unsuspected bronchiectasis and arteriovenous malformations and will show central endobronchial lesions in many cases. High-resolution chest CT scanning is the test of choice for suspected small peripheral malignancies. CT angiography has become the initial test of choice for evaluating patients with suspected pulmonary embolism, although caution should be taken to avoid large contrast loads in patients with even mild chronic kidney disease (serum creatinine > 2.0 g/dL or rapidly rising creatinine in normal range).

Treatment

The management of mild hemoptysis consists of identifying and treating the specific cause. Massive hemoptysis is life-threatening. The airway must be protected, ventilation ensured, and effective circulation maintained. If the location of the bleeding site is known, the patient should be placed in the decubitus position with the involved lung dependent. Uncontrollable hemorrhage warrants rigid bronchoscopy and surgical consultation. In stable patients, flexible bronchoscopy may localize the site of bleeding, and angiography can embolize the involved bronchial arteries. Embolization is effective initially in 85% of cases, although rebleeding may occur in up to 20% of patients over the following year. The anterior spinal artery arises from the bronchial artery in up to 5% of people, and paraplegia may result if it is inadvertently cannulated.

When to Refer

- When bronchoscopic evaluation of lower respiratory tract is required, refer patients to a pulmonologist.
- Patients should be referred to an otolaryngologist for evaluation of upper respiratory tract bleeding source.
- Patients with severe coagulopathy complicating management should be referred to a hematologist.

When to Admit

- To stabilize bleeding process in patients at risk for or experiencing massive hemoptysis.
- To correct disordered coagulation (clotting factors or platelets, or both).
- To stabilize gas exchange.

Chest Pain

Essential Inquiries

- Chest pain onset, character, location/size, duration, periodicity, and exacerbators.
- Shortness of breath.
- Vital signs.
- Chest and cardiac examination.
- Electrocardiography.

- Biomarkers of myocardial necrosis.

General Considerations

Chest pain (or chest discomfort) is a common symptom that can occur as a result of cardiovascular, pulmonary, pleural, or musculoskeletal disease, esophageal or other gastrointestinal disorders, or anxiety states. The frequency and distribution of life-threatening causes of chest pain, such as acute coronary syndrome (ACS), pericarditis, aortic dissection, pulmonary embolism, pneumonia, and esophageal perforation, vary substantially between clinical settings. Systemic lupus erythematosus, rheumatoid arthritis, and HIV are conditions that until only recently have been recognized as conferring a strong risk for coronary artery disease. Because pulmonary embolism can present with a wide variety of symptoms, consideration of the diagnosis and rigorous risk factor assessment for venous thromboembolism (VTE) is critical. Classic VTE risk factors include cancer, trauma, recent surgery, prolonged immobilization, pregnancy, oral contraceptives, and family history and prior history of VTE. Other conditions associated with increased risk of pulmonary embolism include CHF and COPD. Although uncommon in the office setting, delays in diagnosing life-threatening causes of chest pain can result in serious morbidity and mortality.

Clinical Findings

Symptoms

Myocardial ischemia is usually described as dull, aching sensation of "pressure," "tightness," "squeezing," or "gas," rather than as sharp or spasmodic. Ischemic symptoms usually subside within 5–20 minutes but may last longer. Progressive symptoms or symptoms at rest may represent unstable angina due to coronary plaque rupture and thrombosis. Prolonged chest pain episodes might represent myocardial infarction, although up to one-third of patients with acute myocardial infarction do not report chest pain. When present, pain due to myocardial ischemia is commonly accompanied by a sense of anxiety or uneasiness. The location is usually retrosternal or left precordial. Because the heart lacks somatic innervation, precise localization of pain due to cardiac ischemia is difficult; the pain is commonly referred to the throat, lower jaw, shoulders, inner arms, upper abdomen, or back. Ischemic pain may be precipitated or exacerbated by exertion, cold temperature, meals, stress, or combinations of these factors and is usually relieved by rest. However, many episodes do not conform to these patterns; and atypical presentations of ACS are more common in the elderly, women, and persons with diabetes. Other symptoms that are associated with ACS include shortness of breath; dizziness; a feeling of impending doom; and vagal symptoms, such as nausea and diaphoresis. In the elderly, fatigue is a common presenting complaint of ACS. Likelihood ratios for cardinal symptoms considered in the evaluation of acute myocardial infarction are summarized in Table 2–4.

Table 2–4. Likelihood ratios (LRs) for clinical features associated with acute myocardial infarction.

Clinical Feature	**LR+ (95% CI)**
History	
Chest pain that radiates to the left arm	2.3 (1.7–3.1)
Chest pain that radiates to the right shoulder	2.9 (1.4–3.0)
Chest pain that radiates to both arms	7.1 (3.6–14.2)
Pleuritic chest pain	0.2 (0.2–0.3)
Sharp or stabbing chest pain	0.3 (0.2–0.5)
Positional chest pain	0.3 (0.2–0.4)
Chest pain reproduced by palpation	0.2–0.4[1]
Nausea or vomiting	1.9 (1.7–2.3)
Diaphoresis	2.0 (1.9–2.2)
Physical examination	
Systolic blood pressure 80 mm Hg	3.1 (1.8–5.2)
Pulmonary crackle	2.1 (1.4–3.1)

Third heart sound	3.2 (1.6–6.5)
Electrocardiogram	
Any ST segment elevation (1 mm)	11.2 (7.1–17.8)
Any ST segment depression	3.2 (2.5–4.1)
Any Q wave	3.9 (2.7–7.7)
Any conduction defect	2.7 (1.4–5.4)
New ST segment elevation (1 mm)	5.7–53.9[1]
New ST segment depression	3.0–5.2[1]
New Q wave	5.3–24.8[1]
New conduction defect	6.3 (2.5–15.7)

[1] Heteregenous studies do not allow for calculation of a point estimate.

Adapted, with permission, from Panju AA et al. The rational clinical examination. Is this patient having a myocardial infarction? JAMA. 1998 Oct 14;280(14):1256–63.

Hypertrophy of either ventricle or aortic stenosis may also give rise to chest pain with less typical features. Pericarditis may produce pain that is greater when supine than upright and may increase with respiration, coughing, or swallowing. Pleuritic chest pain is usually not ischemic, and pain on palpation should signal a musculoskeletal cause. Aortic dissection classically produces an abrupt onset of tearing pain of great intensity that often radiates to the back; however, this classic presentation occurs in a small proportion of cases. Anterior aortic dissection can also lead to myocardial or cerebrovascular ischemia.

Pulmonary embolism has a wide range of clinical presentations, with chest pain present in only 75% of cases. The chief objective in evaluating patients with suspected pulmonary embolism is to assess the patient's clinical risk for VTE based on medical history and associated signs and symptoms (see above and Chapter 9: Pulmonary Disorders). Esophageal perforation of the thoracic region is another cause of chest pain, with most cases resulting from medical procedures of the esophagus.

Physical Examination

Findings on physical examination can occasionally yield important clues to the underlying cause of chest pain; however, a normal physical examination should never be used as the sole basis for ruling-out most diagnoses, particularly ACS and aortic dissection. Vital sign measurement, including pulse oximetry, is always the first step for assessing the urgency and tempo of the subsequent examination and diagnostic work-up.

Findings that increase the likelihood of ACS include diaphoresis, hypotension, S3 or S4 gallop, pulmonary crackles, or elevated jugular venous pressure (see Table 2–4). Although chest pain that is reproducible or worsened with palpation strongly suggests a musculoskeletal cause, up to 15% of patients with ACS will have reproducible chest wall tenderness. Pointing to the location of the pain with one finger has been shown to be highly correlated with nonischemic chest pain. Aortic dissection can result in differential blood pressures (> 20 mm Hg), pulse amplitude deficits, and new diastolic murmurs. Although hypertension is considered the rule in patients with aortic dissection, systolic blood pressure < 100 mm Hg is present in up to 25% of patients.

A cardiac friction rub represents pericarditis until proven otherwise. It can best be heard with the patient sitting forward at end-expiration. Tamponade should be excluded in all patients with a clinical diagnosis of pericarditis by assessing pulsus paradoxus (a decrease in systolic blood pressure during inspiration > 10 mm Hg) and inspection of jugular venous pulsations. Subcutaneous emphysema is common following cervical esophageal perforation but present in only about one-third of thoracic perforations (ie, those most commonly presenting with chest pain).

The absence of physical examination findings in patients with suspected pulmonary embolism usually serves to *increase* the likelihood of pulmonary embolism, although a normal physical examination is also compatible with the much more common conditions of panic/anxiety disorder and musculoskeletal disease.

Diagnostic Studies

Unless a competing diagnosis can be confirmed, an ECG is warranted in the initial evaluation of most patients with acute chest pain to help exclude ACS. ST segment elevation is the ECG finding that is the strongest predictor of acute myocardial infarction (see Table 2–4); however, up to 20% of patients with ACS can have a normal ECG. A recent study concluded that patients with suspected ACS can be safely removed from cardiac monitoring in the emergency department if they are pain-free at initial physician assessment and have a normal or nonspecific ECG. This decision rule had 100% sensitivity for serious arrhythmia (95% confidence interval, 80–100%), but deserves further validation. Clinically stable patients with cardiovascular disease risk factors, normal ECG, normal cardiac biomarkers and no alternative diagnosis should be followed-up with a timely exercise stress test that includes perfusion imaging. The ECG can also provide evidence for alternative diagnoses, such as pericarditis and pulmonary embolism. Chest radiography is often useful in the evaluation of chest pain, and is always indicated when cough or shortness of breath accompanies chest pain. Findings of pneumomediastinum or new pleural effusion are consistent with esophageal perforation. CT is the study of choice at most centers for the diagnosis of esophageal perforation as well as for aortic dissection (helical CT).

In the evaluation of pulmonary embolism, diagnostic test decisions and results must be interpreted in the context of the clinical likelihood of VTE. A negative D-dimer test is helpful for excluding pulmonary embolism in patients with low clinical probability of VTE (3 month incidence = 0.5%); however, the 3-month risk of VTE among patients with intermediate and high risk of VTE is sufficiently high in the setting of a negative D-dimer test (3.5% and 21.4%, respectively) to warrant further imaging given the life-threatening nature of this condition if left untreated. CT angiography (with helical or multidetector CT imaging) has replaced ventilation-perfusion scanning as the preferred diagnostic test for pulmonary embolism, having approximately 90–95% sensitivity and 95% specificity for detecting pulmonary embolism (compared with pulmonary angiography). However, according to guidelines published by the American Academy of Family Physicians and the American College of Physicians (AAFP/ACP), the sensitivity of helical CT is probably not sufficiently high to exclude pulmonary embolism among patients with high clinical probability of VTE, in whom lower extremity ultrasound or pulmonary angiogram may be appropriate. When ventilation-perfusion scanning is performed, only results that are normal or high probability are useful for improving one's clinical assessment of pulmonary embolism.

Panic disorder is a common cause of chest pain, accounting for up to 25% of cases that present to emergency departments and a higher proportion of cases presenting in primary care office practices. Features that correlate with an increased likelihood of panic disorder include absence of coronary artery disease, atypical quality of chest pain, female sex, younger age, and a high level of self-reported anxiety.

Treatment

Treatment of chest pain should be guided by the underlying etiology. The term "noncardiac chest pain" is used to describe patients who evade diagnosis after receiving extensive work-up. Although under-studied, one small trial of patients with noncardiac chest pain found that about half fulfilled criteria for anxiety or depression and almost half reported symptom improvement with high-dose proton-pump inhibitor therapy.

When to Refer

- Refer patients with poorly controlled, noncardiac chest pain to a pain specialist.
- Refer with sickle cell anemia to a hematologist.

When to Admit

- Failure to adequately exclude (to a sufficient degree) life-threatening causes of chest pain, particularly myocardial infarction, dissecting aortic aneurysm, pulmonary embolism, and esophageal rupture.
- Pain control for rib fracture that impairs gas exchange.

Palpitations

Essential Inquiries

- Forceful, rapid, or irregular beating of the heart.
- Rate, duration, and degree of regularity of heart beat.
- Age at first episode.
- Factors that precipitate or terminate episodes.
- Light-headedness or syncope.
- Chest pain.

General Considerations

Palpitations are defined as an unpleasant awareness of the forceful, rapid, or irregular beating of the heart. They are a common presenting complaint and are usually benign; however, they are occasionally the symptom of a life-threatening arrhythmia. To avoid missing a dangerous cause of the patient's symptom, clinicians sometimes pursue expensive and invasive testing when a conservative diagnostic evaluation is sufficient. The converse is also true; in one study, 54% of patients with supraventricular tachycardia were initially wrongly diagnosed with panic, stress, or anxiety disorder. A disproportionate number of these misdiagnosed patients are women.

Clinical Findings

Symptoms

Although described by patients in a myriad of ways, guiding the patient through a careful description of their palpitations may indicate a mechanism and narrow the differential diagnosis. Pertinent questions include the age at first episode; precipitants; and the rate, duration, and degree of regularity of the heart beat during the subjective palpitations. The examiner can ask the patient to "tap out" the rhythm with their fingers. The circumstances associated with onset and termination can also be helpful in determining the cause. Palpitations that start and stop abruptly suggest supraventricular or ventricular tachycardias. Patient-terminated palpitations using vagal maneuvers (such as the Valsalva maneuver) suggests supraventricular tachycardia.

Three common descriptions of palpitations are (1) "flip-flopping" (or "stop and start"), often caused by premature contraction of the atrium or ventricle, with the perceived "stop" from the pause following the contraction, and the "start" from the subsequent forceful contraction; (2) rapid "fluttering in the chest," with regular "fluttering" suggesting supraventricular or ventricular arrhythmias (including sinus tachycardia) and irregular "fluttering" suggesting atrial fibrillation, atrial flutter, or tachycardia with variable block; and (3) "pounding in the neck" or neck pulsations, often due to "cannon" A waves in the jugular venous pulsations that occur when the right atrium contracts against a closed tricuspid valve.

Palpitations associated with chest pain suggests ischemic heart disease, or if the chest pain is relieved by leaning forward, pericardial disease is suspected. Palpitations associated with light-headedness, presyncope, or syncope suggests hypotension and may signify a life-threatening cardiac arrhythmia. Palpitations that occur regularly with exertion suggests a rate-dependent bypass tract or hypertrophic cardiomyopathy. If a benign etiology for these concerning symptoms cannot be ascertained at the index visit, then ambulatory monitoring or prolonged cardiac monitoring in the hospital might be warranted.

Noncardiac symptoms should also be elicited since the palpitations may be caused by a normal heart responding to a metabolic or inflammatory condition. Weight loss may suggest hyperthyroidism. Palpitations can be precipitated by vomiting or diarrhea that leads to electrolyte disorders and hypovolemia. Palpitations associated with hyperventilation, hand tingling, and nervousness are common when anxiety or panic disorder is the root cause.

Physical Examination

It is uncommon for the clinician to have the opportunity to examine a patient during an episode of palpitations. However, careful cardiovascular examination can find abnormalities that can increase the likelihood of specific cardiac arrhythmias. The midsystolic click of mitral valve prolapse can suggest the diagnosis of a supraventricular arrhythmia as the cause for the palpitations. The harsh holosystolic murmur of hypertrophic cardiomyopathy, which occurs along the left sternal border and increases with the Valsalva maneuver, suggests atrial fibrillation or ventricular tachycardia. The presence of dilated cardiomyopathy, suggested on examination by a displaced and enlarged cardiac point-of-maximal impulse, increases the likelihood of ventricular tachycardia and atrial fibrillation. In patients with chronic atrial fibrillation, in-office exercise (eg, a brisk walk in the hallway) may reveal an intermittent accelerated ventricular response as the cause of the palpitations. The clinician should also look for signs of hyperthyroidism, such as tremulousness, brisk deep tendon reflexes, fine hand tremor, or signs of stimulant drug use (such as dilated pupils or skin or nasal septal lesions).

Diagnostic Studies

The two cardiac studies that are commonly used in the initial evaluation of a patient with palpitations are the 12-lead ECG and ambulatory monitoring devices, such as the Holter monitor or the event recorder.

A 12-lead ECG should be performed on all patients reporting palpitations because it can provide evidence for a wide variety of causes. Although in most instances a specific arrhythmia will not be detected on the tracing, a careful evaluation of the ECG can help the clinician deduce a likely etiology in certain circumstances. For instance, bradyarrhythmias and heart block can be associated with ventricular ectopy or escape beats that may be experienced as palpitations by the patient. Evidence of prior myocardial infarction by history or on ECG (eg, Q waves) increases the patient's risk for nonsustained or sustained ventricular tachycardia. Ventricular preexcitation (Wolff-Parkinson-White syndrome) is suggested by a short PR interval (< 0.20 ms) and delta waves (upsloping PR segments) (see eFigure 2–1.1: ECG). Left ventricular hypertrophy with deep septal Q waves in I, AVL, and V4 through V6 is seen in patients with hypertrophic obstructive cardiomyopathy. The presence of left atrial enlargement as suggested by a terminal P-wave force in V1 more negative than 0.04

msec and notched in lead II reflects a patient at increased risk for atrial fibrillation. A prolonged QT interval and abnormal T-wave morphology suggests the long-QT syndrome (see eFigure 2–1.2: ECG), which puts patients at increased risk for ventricular tachycardia.

eFigure 2–1.1.

Ventricular preexcitation (Wolff-Parkinson-White conduction). (Reproduced, with permission, from Goldschlager N, Goldman MJ: Principles of Clinical Electrocardiography, 13th ed. Originally published by Appleton & Lange. Copyright 1989 by The McGraw-Hill Companies, Inc.)

eFigure 2–1.2.

Typical ECG of a patient with prolonged QT syndrome (leads D1–D3) with markedly abnormal repolarization (QTc 618 ms and ST-T wave abnormalities).

For high-risk patients (Table 2–5), further diagnostic studies are warranted. A step-wise approach has been suggested—starting with ambulatory monitoring devices (Holter monitoring if the palpitations are expected to occur within the subsequent 72-hour period, event monitoring if less frequent), followed by invasive electrophysiologic testing if the ambulatory monitor records a worrisome arrhythmia or if serious arrhythmias are strongly suspected despite normal findings on an appropriate ambulatory monitor.

Table 2–5. Palpitations: Patients at high risk for a cardiovascular cause.
Historical risk factors
Family history of significant arrhythmias
Personal or family history of syncope or resuscitated sudden death
History of myocardial infarction (and likely scarred myocardium)
Physical examination findings
Structural heart disease such as dilated or hypertrophic cardiomyopathies
Valvular disease (stenotic or regurgitant)
ECG findings
Long QT syndrome
Bradycardia

Second- or third-degree heart block
Sustained ventricular arrhythmias

In patients with a prior myocardial infarction, ambulatory cardiac monitoring or signal-averaged-ECG are appropriate next steps to assess ventricular tachycardia. ECG exercise testing is appropriate in patients who have palpitations with physical exertion and patients with suspected coronary artery disease. Echocardiography is useful when physical examination or ECG suggests structural abnormalities or decreased ventricular function.

Differential Diagnosis

When assessing a patient with palpitations in an urgent care setting, the clinician must ascertain whether the symptoms represent (1) an arrhythmia that is minor and transient, (2) significant cardiovascular disease, (3) a cardiac manifestation of a systemic disease such as thyrotoxicosis, or (4) a benign somatic symptom that is amplified by underlying psychosocial characteristics of the patient.

Patients who seek medical attention in the emergency department instead of a medical clinic are more likely to have a cardiac etiology (47% versus 21%), while psychiatric causes are more common among patients with palpitations who seek medical attention in office practices (45% versus 27%). In a study of patients who went to a university medical clinic with the chief complaint of palpitations, etiologies were cardiac in 43%, psychiatric in 31%, and miscellaneous in 10% (including illicit drugs, medications, anemia, thyrotoxicosis, and mastocytosis).

Cardiac arrhythmias that can result in symptoms of palpitations include sinus bradycardia; sinus, supraventricular, and ventricular tachycardia; premature ventricular and atrial contractions; sick sinus syndrome; and advanced atrioventricular block.

Nonarrhythmic cardiac causes of palpitations include valvular heart diseases, such as aortic insufficiency or stenosis, atrial or ventricular septal defect, cardiomyopathy, congenital heart disease, and pericarditis.

Noncardiac causes of palpitations include fever, dehydration, hypoglycemia, anemia, thyrotoxicosis, and pheochromocytoma. Drugs such as cocaine, alcohol, caffeine, and pseudoephedrine can precipitate palpitations, as can prescription medications, including digoxin, phenothiazines, theophylline, and -agonists as well as ephedra-containing herbal remedies or supplements (now banned by the US Food and Drug Administration).

The most common psychiatric causes of palpitations are anxiety and panic disorder. The release of catecholamines during a panic attack or significant stress can trigger an arrhythmia. Asking a single question, "Have you experienced brief periods, for seconds or minutes, of an overwhelming panic or terror that was accompanied by racing heartbeats, shortness of breath, or dizziness?" can help identify patients with panic disorder.

Treatment

After ambulatory monitoring, most patients with palpitations are found to have benign atrial or ventricular ectopy and nonsustained ventricular tachycardia. In patients with structurally normal hearts, these arrhythmias are not associated with adverse outcomes. Abstention from caffeine and tobacco may help. Often, reassurance suffices. If not, or in very symptomatic patients, a trial of a -blocker may be prescribed. For treatment of specific atrial or ventricular arrhythmias, see Chapter 10: Heart Disease.

When to Refer

- For electrophysiologic studies.
- For advice regarding treatment of atrial or ventricular arrhythmias.

When To Admit

- Palpitations associated with syncope or near-syncope, particularly when the patient is aged 75 years or older

and has an abnormal ECG, hematocrit < 30%, shortness of breath, respiratory rate > 24/min, or a history of CHF.
- Patients with risk factors for a serious arrhythmia.

Acute Knee Pain

Essential Inquiries

- Trauma.
- Swelling.
- Fever.
- Symptoms of "locking" or "catching."

General Considerations

The knee is the largest joint in the body and is susceptible to injury from trauma, inflammation from infection and arthritis, and degenerative changes.

The knee is a hinge joint. The joint line exists between the femoral condyles and tibial plateaus. Separating and cushioning these bony surfaces is the lateral and medial **meniscal cartilage**, which functions as a shock absorber during weight bearing. The patella is a large sesamoid bone anterior to the joint line. It is embedded in the quadriceps tendon, and it articulates with the trochlear groove of the femur. The knee is stabilized by the collateral ligaments from varus (lateral collateral ligament) and valgus (medial collateral ligament) stresses.

The tibia is limited in its anterior movement by the anterior cruciate ligament and in its posterior movement by the posterior cruciate ligament. The bursae of the knee are located between the skin and bony prominences. They are sac-like structures with a synovial lining. They act to decrease friction of tendons and muscles as they move over adjacent bony structures. Excessive external pressure, overuse (friction), or inflammation can lead to swelling and pain of the bursae. The most common bursa to cause "knee pain" when inflamed are the prepatellar bursae (located between the skin and patella), and the pes anserine bursa (which is medial and inferior to the patella, just below the tibial plateau).

When there is a knee joint effusion caused by increased fluid in the interarticular space, physical examination will demonstrate swelling in the hollow around the patella and distention into the suprapatellar space (superior to the patella). Joint fluid, when excessive due to synovitis or trauma, can track posteriorly through a potential space, resulting in a popliteal cyst (also called Baker cyst). Other structures that are susceptible to injury and that may cause a patient to report knee pain (but that are not formally part of the knee joint) are the iliotibial band and the fibular head. The iliotibial band is a fascial structure that crosses the prominence of the lateral femoral condyle to attach to the fibular head. The fibular head is susceptible to fracture from trauma.

Clinical Findings

A careful history, coupled with a physical examination that specifically tests anatomic structures is frequently sufficient to establish a diagnosis. Radiologic studies and laboratory testing of aspirated joint fluid, when indicated, can lead to a definitive diagnosis in most patients. The differential diagnosis of knee pain is found in Table 2–6.

Table 2–6. Differential diagnosis of knee pain.
Mechanical dysfunction or disruption
"Internal derangement of the knee"—injury to the menisci or ligaments
Degenerative changes caused by osteoarthritis
Dynamic dysfunction or misalignment of the patella
Fracture as a result of trauma
Increased intra-articular pressure or inflammation
"Internal derangement of the knee"—injury to the menisci or ligaments
Inflammation or infection of the knee joint
Ruptured popliteal ("Baker") cyst
Peri-articular inflammation
"Internal derangement of the knee"—injury to the menisci or ligaments

Prepatellar or anserine bursitis
Ligamentous sprain

History

Evaluation of knee pain should begin with general questions regarding duration and rapidity of symptom onset; a history of trauma; stress or compression from sports, hobbies, or occupation; symptoms of infection (fever, recent bacterial infections, risk factors for sexually transmitted infections [such as gonorrhea] or other bacterial infections [such as staphylococcal infection]). Previous orthopedic problems with, or surgery to, the affected knee should also be specifically queried.

Symptoms

1. Presence of clicking or popping, although nonspecific, may be indicative of osteoarthritis or the patellofemoral syndrome.
2. "Locking" or "catching" when walking suggests meniscal injury.
3. Difficulty bending or swelling of the knee (due to effusion) may indicate synovitis, bursitis, or popliteal (Baker) cyst; however, it may also be associated with meniscal injury if it follows a rotational injury. If acute swelling occurs following a trauma, it may indicate a fracture. If swelling occurs rapidly after a sudden twisting or hyperextension stress, an anterior

cruciate ligament injury should be suspected.
4. Lateral "snapping" with flexion and extension of the knee may indicate inflammation of the iliotibial band.
5. Pain that is worsened when walking downstairs suggests the patellofemoral syndrome, or chondromalacia of the patella, degeneration of the subpatellar cartilage.
6. Pain that occurs when rising after prolonged sitting suggests a problem with tracking of the patella.

Physical Examination

To arrive at an accurate diagnosis, the physical examination should specifically test each anatomic structure.

Localization

Prior to palpation of the knee by the clinician, it is useful for the patient to specifically identify the location of the pain if possible. Specific localization of the painful area can help identify the likely affected structures. Table 2–7 outlines the location of common causes of knee pain.

Table 2–7. Location of common causes of knee pain.
Medial knee pain

Medial compartment osteoarthritis
Anserine bursitis (pain over the medial tibial plateau)
Medial collateral ligament strain
Medial meniscal injury
Anterior knee pain
Patellofemoral syndrome (often bilateral)
Osteoarthritis
Prepatellar bursitis (associated with swelling anterior to the patella)
"Jumper's knee" (pain at the inferior pole of the patella)
Septic arthritis
Gout or other inflammatory disorder
Lateral knee pain
Lateral collateral ligament sprain
Lateral meniscal injury
Lateral knee pain at the femoral condyle–inflammation of the iliotibial band (the iliotibial band syndrome)
Posterior (popliteal) pain
Effusion
Popliteal ("Baker") cyst

Inspection and palpation

To elicit joint line tenderness, flex the patient's knee while he or she is supine and feel for the soft area between the femur and tibia laterally and medially (this is the joint line). Pain and tenderness along the joint line supports the diagnosis of a meniscal injury or osteoarthritis. Pain over the tibial plateau following impact trauma suggests a tibial-plateau fracture (positive likelihood ratio [LR] = 1.1; negative LR = 0.8). Tenderness or swelling, or both, over the medial tibial plateau suggests anserine bursitis. Swelling and erythema over the patella is suggestive of prepatellar bursitis. A knee effusion is suggested by limitation of range of motion, patellar ballotment, fluid wave, concavity or fullness in the suprapatellar space, or loss of peripatellar dimples. Popliteal fullness or pain is indicative of an effusion or popliteal (Baker) cyst. If a popliteal cyst ruptures, there may be calf swelling accompanying the knee effusion. Finally, localized pain or palpable snapping over the lateral femoral condyle is characteristic of iliotibial band syndrome.

Specific Orthopedic Examination Maneuvers

Tests of ligamentous laxity

Ligamentous laxity is best ascertained if the physical examination is performed with relaxed knee muscles. This is most easily accomplished with the patient supine, leg/knee extended, popliteal space supported with a rolled up towel if needed, and the quadriceps femoris muscle relaxed. Otherwise, when significant pain and inflammation exist, maneuvers that test ligamentous laxity can be unreliable since volitional muscle contractions in response to or in anticipation of pain can obscure a positive result.

Collateral ligaments

These ligaments can be examined by two tests.

The valgus stress test

This test assesses stability of the medial collateral ligament. It should be done with the knee in extension, and repeated with the knee flexed at 25 degrees. With the thigh supported by the examination table, buttress the lateral side of the knee with one hand, and pull against the medial distal tibia with the other. This test is considered positive when valgus laxity is noted compared with the other knee. Laxity during this test with a fully extended knee indicates a more severe injury.

The varus stress test

This test assesses stability of the lateral collateral ligament. It should also be done with the knee in extension, and repeated with the knee flexed at 25 degrees. Support the medial side of the knee with one hand, hold and pull the lateral distal tibia with the other (adducting the knee). This test is considered positive when varus laxity is noted compared with the other knee.

Lateral collateral ligament laxity during a test of the fully extended knee indicates a more severe injury.

Anterior cruciate ligaments

The anterior cruciate ligaments can be examined by three tests: the anterior drawer test, the Lachman test, and the pivot shift test. Of the commonly used maneuvers to test for the integrity of the anterior cruciate ligaments, the Lachman and pivot shift tests have the best performance characteristics, whereas the anterior drawer sign is considered the easiest to perform. Small amounts of ligamentous laxity are common and can vary between individuals. Thus, interpretation of results of these maneuvers requires comparison with the contralateral side. A difference of > 1 cm in translation generally indicates a tear of the anterior cruciate ligament.

The anterior drawer test

Have the patient lie supine and flex the knee to 90 degrees. Stabilize the patient's foot by leaning against it (or asking an assistant to do so), and grasp the proximal tibia with both hands around the calf and pull anteriorly. A positive test finds anterior cruciate ligament laxity compared with the unaffected side. (Sensitivity, 48%; specificity, 87%; positive LR = 3.7, negative LR = 0.6.)

The Lachman test

Have the patient lie supine, and flex the knee to 25 degrees. Grasp the distal femur (lateral side), and the proximal tibia with the other hand on the medial side. With the knee in neutral position, stabilize the femur, and pull the tibia anteriorly. Excessive anterior translation of the tibia (compared with the other side) indicates injury to the anterior cruciate ligament. (Sensitivity, 84–87%; specificity, 93%; positive LR = 12.4, negative LR = 0.14.)

The pivot shift test

Place the patient's knee in full extension, and then slowly flex it while applying internal rotation and a valgus stress. Feel for a subluxation at 20–40 degrees of knee flexion. (Positive LR = 20.4, negative LR = 0.4.)

Posterior cruciate ligament

This ligament can be examined by the posterior drawer (or "sag") test. With the patient supine, flex the knee to 90 degrees. Observe the anterior tibial plateau. It should be 10 mm anterior to the femoral condyles. Grasp the proximal tibia with both hands and push the tibia posteriorly. Compare movement, indicating laxity and possible tear of the posterior cruciate ligament, to the uninjured knee.

Tests of meniscal injury

There are two commonly used tests to assess meniscal injury.

The McMurray test

Flex the knee until the patient reports pain. (For this test to be valid, it must be flexed pain-free beyond 90 degrees.) Externally rotate the foot and then extend the knee. Palpating the medial knee for pain or "click" in the medial compartment of the knee is indicative of medial meniscus injury. To test the lateral meniscus, repeat the test, while rotating the foot internally. (Sensitivity, 53%; specificity, 59–97% depending on examiners studied; positive LR = 17.3, negative LR = 0.5.)

The Apley "grind" test

With patient lying prone on the examination table, flex the knee to 90 degrees. Grasp the foot in the palm of the hand. While applying downward pressure on the sole of the foot to axial load the lower leg (thereby compressing the menisci between the femoral condyles and the tibial plateau), carefully rotate the lower leg in a "grinding" motion, assessing for pain.

Testing for patella-femoral syndrome

There are three commonly used tests for the patella-femoral syndrome.

Patellar compression test

If compression of the patella against the femur reproduces the patient's pain (or causes "clicking" perceived by the patient), it is diagnostic of the patella-femoral syndrome.

Patellar grind test

With the patient supine and the knee extended, push the patella inferiorly by grasping the knee superior to the patella and pushing it downward. Ask the patient to contract the quadriceps muscle to oppose this downward translation. Pain or grinding is positive for chondromalacia of the patella.

Patellar apprehension test

Have the patient sit on the end of the examination table. Lift the lower leg into extension (asking the patient to relax the quadriceps muscle). Push the patella laterally, and then flex the knee to 30 degrees. Patellar instability is diagnosed if the patient experiences pain or apprehension.

Radiologic Studies

Under selected circumstances, radiologic studies can be useful in the diagnosis of acute knee pain. Plain radiographs can confirm osteoarthritic changes and identify fractures. MRI can assess soft-tissue injuries that may need urgent surgery (eg, ruptured anterior cruciate ligament). However, most causes of acute knee pain can be diagnosed in the absence of radiographic studies (see

Ottawa Knee Rules below).

Plain knee radiographs

Osteoarthritis

Obtain bilateral weight-bearing knee films. Changes due to osteoarthritis include diminished width of articular cartilage, presence of osteophytes, and subchondral sclerosis.

Acute fracture

In patients with acute knee trauma, the decision to obtain radiographs to exclude fracture should be guided by the "Ottawa Knee Rules" (Table 2–8) (sensitivity, ~100%; specificity 49%).

Table 2–8. "Ottawa Knee Rules": Indications for radiographs in acute knee injury.
Consider knee radiography if any one of the following features is present:
Age 55 years
Fibular head tenderness
Isolated patella tenderness
Impaired knee flexion to 90 degrees
Inability to bear weight for four steps after the injury and

in the emergency department

Reproduced, with permission, from Stiell IG et al. Prospective validation of a decision rule for the use of radiography in acute knee injuries. JAMA. 1996;275:611–5.

Patella-femoral syndrome

Although usually unnecessary for establishing the diagnosis of the patella-femoral syndrome, bilateral "sunrise" radiographs of the patellofemoral joint suggest chondromalacia of the patella when any of the following are present: subluxation, subchondral bony changes, osteophytes, or loose bodies. These findings are especially evident in advanced cases.

MRI of the knee

MRI of the knee is the most sensitive test for diagnosis and evaluation of soft tissue pathology, including injuries to the ligaments and menisci. MRI is useful to confirm an anterior cruciate ligament tear suspected from the history and Lachman test. MRI is helpful in determining the need for arthroscopy and surgery. It may also detect fracture after trauma when it is clinically suspected but plain radiographs are negative.

Arthrocentesis (see Chapter 20: Musculoskeletal &

Immunologic Disorders)

If a knee joint effusion is present, arthrocentesis and analysis of joint fluid is useful diagnostically, particularly for distinguishing infection from sterile inflammation (see Table 20–2). In addition, when knee pain is due to an effusion, joint fluid aspiration has therapeutic value by improving flexion and reducing pain. To avoid infecting the joint, arthrocentesis should not be performed when the aspirating needle will penetrate an active infection of the skin, such as cellulitis or abscess. It is also contraindicated if there is a significant coagulopathy, such as excessive anticoagulation with warfarin.

Arthrocentesis must be performed promptly to rule out an infection when acute knee pain with effusion is present as well as when inflammation is present and the patient is unable to actively flex the joint. An anterior cruciate ligament tear often leads to hemarthrosis. Thus, a physical examination that shows anterior cruciate ligament laxity combined with a joint aspiration that demonstrates bloody fluid is diagnostic of an anterior cruciate ligament tear.

Arthrocentesis and joint fluid analysis demonstrating crystals will lead to the diagnosis of gout (negatively birefringent, needle-shaped crystals) or pseudogout (positively birefringent, rectangular-shaped crystals). In bland knee joint effusions, removal of excessive joint fluid improves joint range of motion (flexion) and patient comfort.

Treatment

If infection, fracture, and ligamentous or meniscal tear are excluded, many acute knee conditions improve with conservative treatment consisting of low-impact activities and exercises (such as swimming, biking, walking, or cross-country skiing) to improve muscular strength and flexibility. For example, the patella-femoral syndrome is effectively treated with exercises to strengthen the vastus medialis muscle and with stretching of the hamstring and quadriceps muscles. A formal physical therapy program is usually not required.

The initial drugs of choice for the treatment of pain in knee osteoarthritis are acetaminophen and topical capsaicin. If a traditional nonsteroidal anti-inflammatory drug (NSAID) is indicated, the choice should be based on cost. The cyclooxygenase (COX)-2 inhibitor, celecoxib, is no more effective than traditional NSAIDs; it may offer short-term, but probably not long-term, advantage in preventing gastrointestinal complications. Due to its cost and potential risk of heart attack, this COX-2 inhibitor should be reserved for carefully selected patients.

When to Refer

Refer patients with fracture or internal derangement of the knee to an orthopedist.

When to Admit

- Admit patients with septic joints (in consultation with rheumatologist or orthopedist).
- Admit patients who are unable to ambulate and who lack home support for performing activities of daily living.

Lower Extremity Edema

Essential Inquiries

- History of venous thromboembolism.

- Symmetry.
- Pain.
- Dependence.
- Skin findings.

General Considerations

Acute and chronic lower extremity edema present important diagnostic and treatment challenges. Lower extremities can swell in response to increased venous or lymphatic pressures, decreased intravascular oncotic pressure, increased capillary leak, and local injury or infection. **Chronic venous insufficiency** is by far the most common cause, affecting up to 2% of the population, and the incidence of venous insufficiency has not changed during the past 25 years. Venous insufficiency is a common complication of DVT; however, only a small number of patients with chronic venous insufficiency report a history of this disorder. Venous ulcer formation commonly affects patients with chronic venous insufficiency, and management of venous ulceration is labor-intensive and expensive.

Clinical Findings

Symptoms and Signs

Normal lower extremity venous pressure (in the erect position: 80 mm Hg in deep veins, 20–30 mm Hg in superficial veins) and cephalad venous blood flow require competent bicuspid venous valves, effective muscle contractions, and normal respirations. When one or more of these components fail, venous hypertension may result. Chronic exposure to elevated venous pressure by the postcapillary venules in the legs leads to leakage of fibrinogen and growth factors into the interstitial space, leukocyte aggregation and activation, and obliteration of the cutaneous lymphatic network. These changes account for the brawny, fibrotic skin changes observed in patients with chronic venous insufficiency, and the predisposition toward skin ulceration, particularly in the medial malleolar area.

Among common causes of lower extremity swelling, DVT is the most life-threatening. Clues suggesting DVT include a history of cancer, recent limb immobilization, or confinement to bed for at least 3 days following major surgery within the past month (Table 2–9). A search for alternative explanations is equally important in excluding DVT. Bilateral involvement and significant improvement upon awakening favor systemic causes (eg, venous insufficiency, CHF, and cirrhosis). "Heavy legs" are the most frequent symptom among patients with chronic venous insufficiency, followed by itching. Pain, particularly if severe, is uncommon in uncomplicated venous insufficiency. Lower extremity swelling and inflammation in a limb recently affected by DVT could represent anticoagulation failure and thrombus recurrence but more often are caused by **postphlebitic syndrome** with valvular incompetence. Other causes of a painful, swollen calf include ruptured popliteal cyst, calf strain or trauma, and cellulitis.

Table 2–9. Risk stratification of adults referred for ultrasound to rule out DVT.
Step 1: Calculate risk factor score
Score 1 point for each
Untreated malignancy
Paralysis, paresis, or recent plaster immobilization
Recently bedridden for > 3 days due to major surgery within 4 weeks
Localized tenderness along distribution of deep venous system
Entire leg swelling
Swelling of one calf > 3 cm more than the other (measured 10 cm below tibial tuberosity)
Pitting edema
Collateral superficial (nonvaricose) veins
Alternative diagnosis as likely as or more likely than DVT: subtract 2 points
Step 2: Obtain ultrasound

Score	Ultrasound Positive	Ultrasound Negative
0	Confirm with venogram	DVT ruled out
1–2	Treat for DVT	Repeat ultrasound in 3–7 days
3	Treat for DVT	Confirm with venogram

DVT = deep venous thrombosis.

Lower extremity swelling is a familiar complication of therapy with calcium channel blockers (particularly felodipine and amlodipine), thioglitazones, and minoxidil. Bilateral lower extremity edema can be a presenting symptom of nephrotic syndrome or volume overload caused by renal failure. Prolonged airline flights (> 10 hours) are associated with increased risk of edema. In those with low to medium risk of thromboembolism (eg, women taking oral contraceptives), long flights are associated with a 2% incidence of asymptomatic popliteal DVT.

Physical Examination

Physical examination should include assessment of the heart, lungs, and abdomen for evidence of pulmonary hypertension (primary, or secondary to chronic lung disease), CHF, or cirrhosis. Some patients with the latter have pulmonary hypertension without lung disease. There is a spectrum of skin findings related to chronic venous insufficiency that depends on the severity and chronicity of the disease, ranging from hyperpigmentation and stasis dermatitis to abnormalities highly specific for chronic venous insufficiency: lipodermatosclerosis (thick brawny skin; in advanced cases, the lower leg resembles an inverted champagne bottle) and atrophie blanche (small depigmented macules within areas of heavy pigmentation). The size of both calves should be measured 10 cm below the tibial tuberosity and elicitation of pitting and tenderness performed. Swelling of the entire leg or swelling of one leg 3 cm more than the other suggests deep venous obstruction. In normal persons, the left calf is slightly larger than the right as a result of the left common iliac vein coursing under the aorta.

An ulcer located over the medial malleolus is a hallmark of chronic venous insufficiency but can be due to other causes. Shallow, large, modestly painful ulcers are characteristic of venous insufficiency, whereas small, deep, and more painful ulcers are more apt to be due to arterial insufficiency, vasculitis, or infection (including cutaneous diphtheria). Diabetic vascular ulcers, however, may be painless. When an ulcer is on the foot or above the mid calf, causes other than venous insufficiency should be considered.

Diagnostic Studies

Most causes of lower extremity swelling can be demonstrated with color duplex ultrasonography. Patients without an obvious cause of acute lower extremity swelling (eg, calf strain) should have an ultrasound performed, since DVT is difficult to exclude on clinical grounds. Recently, a predictive rule has been developed that allows a clinician to exclude a lower extremity DVT in patients without an ultrasound if the patient has low pretest probability for DVT and has a negative sensitive D-dimer test (the "Wells rule"). Assessment of the ankle-brachial pressure index (ABPI) is important in the management of chronic venous insufficiency, since peripheral arterial disease may be exacerbated by compression therapy. This can be performed at the same time as ultrasound. Caution is required in interpreting the results of ABPI in older patients and diabetics due to decreased compressibility of their arteries. A dipstick urine test that is strongly positive for protein can suggest nephrotic syndrome, and a serum creatinine can help estimate kidney function.

Differential Diagnosis

Possible causes include chronic venous insufficiency, DVT, cellulitis, musculoskeletal disorders (Baker cyst rupture, gastrocnemius tear or rupture), lymphedema, CHF, cirrhosis, and nephrotic syndrome as well as side effects from calcium channel blockers, minoxidil, or thioglitazones.

Treatment

Treatment of lower extremity edema should be guided by the underlying etiology. See relevant chapters for treatment of edema in patients with congestive heart failure (Chapter 10: Heart Disease), nephrosis (Chapter 22: Kidney Disease), cirrhosis (Chapter 16: Liver, Biliary Tract, & Pancreas Disorders), and lymphedema (Chapter 12: Blood Vessel & Lymphatic Disorders). Edema resulting from calcium channel blocker therapy responds to concomitant therapy with ACE inhibitors or angiotensin receptor blockers.

In patients with chronic venous insufficiency without a comorbid volume overload state (eg, CHF), it is best to avoid diuretic therapy. These patients have relatively decreased intravascular volume, and administration of diuretics may result in acute renal insufficiency and oliguria. The most effective treatment involves (1) leg elevation, above the level of the heart, for 30 minutes three to four times daily, and during sleep; and (2) compression therapy. A wide variety of stockings and devices are effective in decreasing swelling and preventing ulcer formation. They should be put on with awakening, before hydration forces result in edema. Horse chestnut seed extract has been shown in several randomized trials to be equivalent to compression stockings, and can be quite useful in nonambulatory patients. Patients with decreased ABPI should be managed in concert with a vascular surgeon. Compression stockings (12–18 mm Hg at the ankle) are effective in preventing edema and asymptomatic thrombosis associated with long airline flights in low- to medium-risk persons.

When to Refer

- Chronic lower extremity ulcerations requiring specialist wound care.
- Nephrotic syndrome should be managed with nephrology consultation.
- When there is coexisting severe arterial insufficiency (claudication) complicating treatment with compression stockings.

When to Admit

- Pending definitive diagnosis in patients at high risk for DVT with normal lower extremity ultrasound.
- Concern for impending compartment syndrome.
- Severe edema that impairs ability to ambulate or perform activities of daily living.

Fever & Hyperthermia

Essential Inquiries

- Age
- Localizing symptoms.
- Weight loss.
- Joint pain.
- Injection substance use.
- Immunosuppression or neutropenia.
- History of cancer.
- Medications.
- Travel.

General Considerations

The average normal oral body temperature taken in mid-morning is 36.7 °C (range 36–37.4 °C). This spectrum includes a mean and 2 standard deviations, thus encompassing 95% of a normal population, measured in mid-morning (normal diurnal temperature variation is 0.5–1 °C). The normal rectal or vaginal temperature is 0.5 °C higher than the oral temperature, and the axillary temperature is correspondingly lower. Rectal temperature is more reliable than oral temperature, particularly in mouth breathers or in tachypneic states.

Fever is a regulated rise to a new "set point" of body temperature. When proper stimuli act on appropriate monocyte-macrophages, these cells elaborate pyrogenic cytokines, causing elevation of the set point through effects in the hypothalamus. These cytokines include interleukin-1 (IL-1), tumor necrosis factor (TNF), interferon- , and interleukin-6 (IL-6). The elevation in temperature results from either increased heat production (eg, shivering) or decreased loss (eg, peripheral vasoconstriction). Body temperature in cytokine-induced fever seldom exceeds 41.1 °C unless there is structural damage to hypothalamic regulatory centers.

Fever

Fever as a symptom provides important information about the presence of illness—particularly infections—and about changes in the clinical status of the patient. The fever pattern, however, is of marginal value for most specific diagnoses except for the relapsing fever of malaria, borreliosis, and occasional cases of lymphoma, especially Hodgkin disease. Furthermore, the degree of temperature elevation does not necessarily correspond to the severity of the illness. In general, the febrile response tends to be greater in children than in adults. In older persons, neonates, and in persons receiving certain medications (eg, NSAIDs or corticosteroids), a normal temperature or even hypothermia may be observed. Markedly elevated body temperature may result in profound metabolic disturbances. High temperature during the first trimester of pregnancy may cause birth defects, such as anencephaly. Fever increases insulin requirements and alters the metabolism and disposition of drugs used for the treatment of the diverse diseases associated with fever.

Hyperthermia

Hyperthermia—not mediated by cytokines—occurs when body metabolic heat production or environmental heat load exceeds normal heat loss capacity or when there is impaired heat loss; heat stroke is an example. Body temperature may rise to levels (> 41.1 °C) capable of producing irreversible protein denaturation and resultant brain damage; no diurnal variation is observed.

Neuroleptic malignant syndrome is a rare and potentially lethal idiosyncratic reaction to major tranquilizers, particularly haloperidol and fluphenazine; however, it has also been reported with the atypical neuroleptics (such as olanzapine or risperidone). **Serotonin syndrome** resembles neuroleptic malignant syndrome but occurs within hours of ingestion of agents that increase levels of serotonin in the central nervous system, including serotonin reuptake inhibitors, monoamine oxidase inhibitors, tricyclic antidepressants, meperidine, dextromethorphan, bromocriptine, tramadol, lithium, and psychostimulants (such as cocaine, methamphetamine, and MDMA). Clonus and hyperreflexia are more common in serotonin syndrome whereas "lead pipe" rigidity is more common in neuroleptic malignant syndrome. Neuroleptic malignant and serotonin syndromes share common clinical and pathophysiologic similarities to **malignant hyperthermia** of anesthesia (see Chapter 25: Psychiatric Disorders and Chapter 38: Poisoning).

Treatment

Discontinuation of the offending agent is mandatory. Treatment of neuroleptic malignant syndrome includes dantrolene in combination with bromocriptine or levodopa. Treatment of serotonin syndrome includes administration of a central serotonin receptor antagonist—cyproheptadine or chlorpromazine—alone or in combination with a benzodiazepine. In patients for whom it is difficult to distinguish which syndrome is present, treatment with a benzodiazepine may be the safest therapeutic option. Regardless of cause, alcohol sponges, cold sponges, ice bags, ice-water enemas, and ice baths can also help lower body temperature.

Fever of Undetermined Origin

(See Fever of Unknown Origin, Infectious Diseases: Common Problems & Antimicrobial Therapy)

Most febrile illnesses are due to common infections, are short-lived, and are relatively easy to diagnose. In certain instances, however, the origin of the fever may remain obscure ("fever of undetermined origin," FUO) even after protracted diagnostic examination. In upper respiratory tract infections, fever typically lasts no more than 3–5 days, beyond which additional evaluation should be considered. The term "FUO" has traditionally been reserved for unexplained cases of fever exceeding 38.3 °C on several occasions for at least 3 weeks in patients without neutropenia or immunosuppression (see Chapter 30: Common Problems in Infectious Diseases & Antimicrobial Therapy). Some authors have advocated for changing the definition of FUO in frail elderly nursing home patients to a persistent oral or tympanic membrane temperature of 37.2 °C (99 °F) or greater, or persistent rectal temperature of 37.5 °C (99.5 °F) or greater.

After extensive evaluation, 25% of these patients are judged to have chronic or indolent infection, about 25% autoimmune diseases, and about 10% a malignancy; the remainder have miscellaneous other disorders or no diagnosis is reached. With improved imaging and microbiology testing, fewer cases are being attributed to infectious disease and more are being attributed to cancer and autoimmune disease (particularly among the elderly). Long-term follow-up of patients with initially undiagnosed FUO demonstrates that 50% become symptom free during evaluation. In the remainder, a definitive diagnosis is established in 20%, usually within 2 months after investigation, and 30% have persistent or recurring fever for months or even years.

Standardized algorithms for FUO are difficult to extrapolate to the individual patient. Nevertheless, the results of a history, physical examination, routine laboratory tests, and blood cultures provide important diagnostic clues that lead to a definitive diagnosis in most cases. Chest radiography, abdominal ultrasound, and CT scans, often repeated after previous nondiagnostic studies, are most helpful. Radionuclide agents include labeled leukocytes, gallium-67, and radiolabeled human immunoglobulin; however, these tests appear to be most useful in patients with localizing signs of inflammation. There is little or no value to be derived from undirected immunologic, microbiologic, serologic, or endocrinologic studies. In older patients, a temporal artery biopsy is occasionally of use. Newer imaging modalities that may be useful in challenging cases include fluorodeoxyglucose-positron emission tomography imaging.

FUO is commonly associated with AIDS and HIV-related infections, though uncomplicated HIV infection is not a cause of prolonged fever. When FUO is observed in HIV-infected individuals, it usually occurs in the late stages. The most common causes are disseminated *Mycobacterium avium* infection, *P jiroveci* pneumonia, cytomegalovirus infection, disseminated histoplasmosis, and lymphoma.

The differential diagnosis of a febrile illness in the returned traveler is extensive but most commonly includes tropical infections such as malaria, dysentery, hepatitis, and dengue fever. A substantial number of febrile illnesses in travelers are never diagnosed. See Infectious Diseases in Returning Traveler, Chapter 30: Common Problems in Infectious Diseases & Antimicrobial Therapy.

Differential Diagnosis

See Table 2–10. The causes of FUO among elderly patients differ from those in younger patients, and a definitive diagnosis can be achieved in a larger proportion of elderly patients (up to 70%). Although the general diagnostic approach and distribution of infectious and noninfectious causes are roughly similar between age groups, tuberculosis and temporal arteritis are particularly more common causes of FUO in the elderly.

Table 2–10. Differential diagnosis of fever and hyperthermia.
Fever—common causes
Infections: bacterial, viral, rickettsial, fungal, parasitic
Autoimmune diseases
Central nervous system disease, including head trauma and mass lesions

Malignant disease, especially renal cell carcinoma, primary or metastatic liver cancer, leukemia, and lymphoma
Fever—less common causes
Cardiovascular diseases, including myocardial infarction, thrombophlebitis, and pulmonary embolism
Gastrointestinal diseases, including inflammatory bowel disease, alcoholic hepatitis, and granulomatous hepatitis
Miscellaneous diseases, including drug fever, sarcoidosis, familial Mediterranean fever, tissue injury, hematoma, and factitious fever
Hyperthermia
Peripheral thermoregulatory disorders, including heat stroke, malignant hyperthermia of anesthesia, and malignant neuroleptic syndrome

Treatment

Most fever is well tolerated. When the temperature is greater than 40 °C, symptomatic treatment may be required. A reading over 41 °C is likely to be hyperthermia and thus not cytokine mediated, and emergent management is indicated. (See Heat Stroke, Environmental Disorders.)

Measures for Removal of Heat

Alcohol sponges, cold sponges, ice bags, ice-water enemas, and ice baths will lower body temperature. They are more useful in hyperthermia, since patients with cytokine-related fever will attempt to override these therapies.

Antipyretic Drugs

Antipyretic therapy is not needed except for patients with marginal hemodynamic status. Aspirin or acetaminophen, 325–650 mg every 4 hours, is effective in reducing fever. These drugs are best administered continuously rather than as needed, since "prn" dosing results in periodic chills and sweats due to fluctuations in temperature caused by varying levels of drug.

Antimicrobial Therapy

In most febrile patients, empiric antibiotic therapy should be deferred pending further evaluation. However, empiric antibiotic therapy is sometimes warranted. Prompt broad-spectrum antimicrobials are indicated for febrile patients who are clinically unstable, even before infection can be documented. These include patients with hemodynamic instability, those with neutropenia (neutrophils < 500/mcL), others who are asplenic (surgically or secondary to sickle cell disease) or immunosuppressed (including individuals taking systemic corticosteroids, azathioprine, cyclosporine, or other immunosuppressive medications), and those who are HIV infected (see

Chapter 31: HIV Infection & AIDS). For treatment of fever during neutropenia following chemotherapy, outpatient parenteral antimicrobial therapy with an agent such as ceftriaxone can be provided effectively and safely. If a fungal infection is suspected in patients with prolonged fever and neutropenia, fluconazole is an equally effective but less toxic alternative to amphotericin B.

When to Refer

- Once the diagnosis of FUO is made, referral to infectious disease specialist or rheumatologist may be appropriate to guide specific additional tests.

When to Admit

- Malignant hyperthermia.
- Heat stroke.
- For measures to control temperature when it is > 41 °C or when associated with seizure or other mental status changes.

Involuntary Weight Loss

Essential Inquiries

- Age.
- Caloric intake.
- Fever.
- Change in bowel habits.
- Secondary confirmation (eg, changes in clothing size).
- Substance use.
- Age-appropriate cancer screening history.

General Considerations

Body weight is determined by a person's caloric intake, absorptive capacity, metabolic rate, and energy losses. The metabolic rate can be affected by a multitude of medical conditions through the release of various cytokines such as cachectin and interleukins. Body weight normally peaks by the fifth or sixth decade and then gradually declines at a rate of 1–2 kg per decade. In NHANES II, a national survey of community-dwelling elders (age 50–80 years), recent involuntary weight loss (> 5% usual body weight) was reported by 7% of respondents, and this was associated with a 24% higher mortality.

Etiology

Involuntary weight loss is regarded as clinically significant when it exceeds 5% or more of usual body weight over a 6- to 12-month period and often indicates serious physical or psychological illness. Physical causes are usually evident during the initial evaluation. Cancer (about 30%), gastrointestinal disorders (about 15%), and dementia or depression (about 15%) are the most common causes. When an adequately nourished-appearing patient complains of weight loss, inquiry should be made about exact weight changes (with approximate dates) and about changes in clothing size. Family members can provide confirmation of weight loss, as can old documents such as driver's licenses. A mild, gradual weight loss occurs in some older individuals. It is due to changes in body composition, including loss of height and lean body mass and lower basal metabolic rate, leading to decreased energy requirements. However, rapid involuntary weight loss is predictive of morbidity and mortality in any population. In addition to various disease states, causes in older individuals include loss of teeth and consequent difficulty with chewing, alcoholism, and social isolation.

Clinical Findings

Once the weight loss is established, the history, medication profile, physical examination, and conventional laboratory and radiologic investigations (such as complete blood count, serologic tests including HIV, thyroid-stimulating hormone (TSH) level, urinalysis, fecal occult blood test, chest radiography, and upper gastrointestinal series) usually reveal the cause. When these tests are normal, the second phase of evaluation should focus on more definitive gastrointestinal investigation (eg, tests for malabsorption; endoscopy) and cancer screening (eg, Papanicolaou smear, mammography, prostate specific antigen [PSA]).

If the initial evaluation is unrevealing, follow-up is preferable to further diagnostic testing. Death at 2-year follow-up was not nearly as high in patients with unexplained involuntary weight loss (8%) as in those with weight loss due to malignant (79%) and established nonmalignant diseases (19%). Psychiatric consultation should be considered when there is evidence of depression, dementia, anorexia nervosa, or other emotional problems. Ultimately, in approximately 15–25% of cases, no cause for the weight loss can be found.

Differential Diagnosis

Malignancy, gastrointestinal disorders (eg, malabsorption, pancreatic insufficiency), dementia, depression, anorexia nervosa, hyperthyroidism, alcoholism, and social isolation are all established causes. "Meals on Wheels" is a useful mnemonic for remembering the common treatable causes of involuntary weight loss in the elderly (see box).

Box 2–1. Meals on Wheels: A mnemonic for common treatable causes of involuntary weight loss in the elderly.

Medication effects

Emotional problems, especially depression

Anorexia tardive (nervosa), alcoholism

Late-life paranoia

Swallowing disorders

Oral factors (eg, poorly fitting dentures, cavities)

No money

Wandering and other dementia-related behaviors

Hyperthyroidism, hypothyroidism, hyperparathyroidism, hypoadrenalism

Enteric problems (eg, malabsorption, gallstones)

Eating problems (eg, inability to feed self)

Low-salt, low-cholesterol diets

Social problems (eg, isolation, inability to obtain

preferred foods)

Adapted, with permission, from Morley JE et al. Nutritional issues in nursing home care. Ann Intern Med. 1995 Dec 1;123(11):850–9.

Treatment

Weight stabilization occurs in most surviving patients with both established and unknown causes of weight loss through treatment of the underlying disorder and caloric supplementation. Nutrient intake goals are established in relation to the severity of weight loss, in general ranging from 30 to 40 kcal/kg/d. In order of preference, route of administration options include oral, temporary nasojejunal tube, or percutaneous gastric or jejunal tube. Parenteral nutrition is reserved for patients with serious associated problems. A variety of pharmacologic agents have been proposed for the treatment of weight loss. These can be categorized into appetite stimulants (corticosteroids, progestational agents, dronabinol, and serotonin antagonists); anabolic agents (growth hormone and testosterone derivatives); and anticatabolic agents (omega-3 fatty acids, pentoxifylline, hydrazine sulfate, and thalidomide).

When to Refer

- Weight loss caused by malabsorption.
- Persistent nutritional deficiencies despite adequate supplementation.
- Weight loss as a result of anorexia or bulimia.

When to Admit

- Severe protein-energy malnutrition, including the syndromes of kwashiorkor and marasmus.
- Vitamin deficiency syndromes.
- Cachexia with anticipated progressive weight loss secondary to unmanageable psychiatric disease.
- To carefully manage electrolyte and fluid replacement in protein-energy malnutrition and avoid "re-feeding syndrome."

Fatigue & Chronic Fatigue Syndrome

Essential Inquiries

- Weight loss.
- Fever.
- Sleep-disordered breathing.
- Medications.
- Substance use.

General Considerations

Fatigue, as an isolated symptom, accounts for 1–3% of visits to generalists. The symptom of fatigue is often poorly described and less well defined by patients than symptoms associated with specific dysfunction of organ systems. Fatigue or lassitude and the closely related complaints of weakness, tiredness, and lethargy are often attributed to overexertion, poor physical conditioning, sleep disturbance, obesity, undernutrition, and emotional problems. A history of the patient's daily living and working habits may obviate the need for extensive and unproductive diagnostic studies.

Clinical Findings

Fatigue

Clinically relevant fatigue is composed of three major components: generalized weakness (difficulty in initiating activities); easy fatigability (difficulty in completing activities); and mental fatigue (difficulty with concentration and memory). Important diseases that can cause fatigue include hyperthyroidism and hypothyroidism, CHF, infections (endocarditis, hepatitis), COPD, sleep apnea, anemia, autoimmune disorders, irritable bowel syndrome, and cancer. Alcoholism, side effects from such drugs as sedatives and -blockers may be the cause. Psychological conditions, such as insomnia, depression, anxiety, panic attacks, dysthmia, and somatization disorder, may cause fatigue. Common outpatient infectious causes include mononucleosis and sinusitis. These conditions are usually associated with other characteristic signs, but patients may emphasize fatigue and not reveal their other symptoms unless directly asked. The lifetime prevalence of significant fatigue (present for at least 2 weeks) is about 25%. Fatigue of unknown cause or related to psychiatric illness exceeds that due to physical illness, injury, medications, drugs, or alcohol (eFigure 2–1.3: illustration).

eFigure 2–1.3.

Overlapping diagnoses. Prolonged fatigue states are found in fibromyalgia, irritable bowel syndrome, anxiety, and depression as well as chronic fatigue syndrome. (Reproduced, with permission, from Chronic fatigue syndrome. Clinical practice guidelines–2002. Med J Aust. 2002 May 6;176 Suppl:S23–56 2002;176:S17.)

Chronic Fatigue Syndrome

A working case definition of chronic fatigue syndrome indicates that it is not a homogeneous abnormality, and there is no single pathogenic mechanism (Figure 2–2: illustration). No physical finding or laboratory test can be used to confirm the diagnosis of this disorder.

Figure 2–2

Evaluation and classification of unexplained chronic fatigue. (CBC, complete blood count; ESR, erythrocyte sedimentation rate; ALT, alanine aminotransferase; Ca^{2+}, calcium; PO$_4^{3-}$, phosphate; BUN, blood urea nitrogen; TSH, thyroid-stimulating hormone; UA, urinalysis.)

(Modified and reproduced, with permission, from Fukuda K et al. The chronic fatigue syndrome: a comprehensive approach to its definition and study. Ann Intern Med. 1994 Dec 15;121(12):953–9.)

With regard to its pathophysiology, early theories postulated an infectious or immune dysregulation mechanism. Persons with confirmed chronic fatigue syndrome report a much greater frequency of childhood trauma and psychopathology and demonstrate higher levels of emotional instability and self-reported stress than non-fatigued controls. Neuropsychological, neuroendocrine, and brain imaging studies have confirmed the occurrence of neurobiologic abnormalities in most patients. Sleep disorders have been reported in 40–80% of patients with chronic fatigue syndrome, but their treatment has provided only modest benefit, suggesting that it is an effect rather than a cause of the fatigue. MRI scans may show brain abnormalities on T_2-weighted images—chiefly small, punctate, subcortical white matter hyperintensities, predominantly in the frontal lobes. Veterans of the Gulf War show a tenfold greater incidence of chronic fatigue syndrome compared with nondeployed military personnel.

In evaluating chronic fatigue, after the history and physical examination process is completed, standard investigation includes complete blood count, erythrocyte sedimentation rate, serum chemistries—blood urea nitrogen (BUN), electrolytes, glucose, creatinine, and calcium; liver and thyroid function tests—antinuclear antibody, urinalysis, and tuberculin skin test; and screening questionnaires for psychiatric disorders. Other tests to be performed as clinically indicated are serum cortisol, rheumatoid factor, immunoglobulin levels, Lyme serology in endemic areas, and tests for HIV antibody. More extensive testing is usually unhelpful, including antibody to Epstein-Barr virus. There may be an abnormally high rate of postural hypotension; some of these patients report response to increases in dietary sodium as well as antihypotensive agents such as fludrocortisone, 0.1 mg/d.

Treatment

Fatigue

Management of fatigue involves identification and treatment of conditions that contribute to fatigue, such as cancer, pain, depression, disordered sleep, weight loss, and anemia. Resistance training and aerobic exercise lessens fatigue and improves performance for a number of chronic conditions associated with a high prevalence of fatigue, including CHF, COPD, arthritis, and cancer. Continuous positive airway pressure is an effective treatment for obstructive sleep apnea. Psychostimulants such as methylphenidate have shown inconsistent results in randomized trials of treatment of cancer-related fatigue.

Chronic Fatigue Syndrome

A variety of agents and modalities have been tried for the treatment of chronic fatigue syndrome. Acyclovir, intravenous immunoglobulin, nystatin, and low-dose hydrocortisone/fludrocortisone do not improve symptoms. There is a greater prevalence of past and current psychiatric diagnoses in patients with this syndrome. Affective disorders are especially common, but fluoxetine alone, 20 mg daily, is not beneficial. Patients with chronic fatigue syndrome have benefited from a comprehensive multidisciplinary intervention, including optimal medical management, treating any ongoing affective or anxiety disorder pharmacologically, and implementing a comprehensive cognitive-behavioral treatment program. **Cognitive-behavioral therapy,** a form of nonpharmacologic treatment emphasizing self-help and aiming to change perceptions and behaviors that may perpetuate symptoms and disability, is helpful. Although few patients are cured, the treatment effect is substantial. Response to cognitive-behavioral therapy is not predictable on the basis of severity or duration of chronic fatigue syndrome, although patients with low interest in psychotherapy rarely benefit. Graded exercise has also been shown to improve functional work capacity and physical function. At present, intensive individual cognitive-behavioral therapy administered by a skilled therapist and graded exercise are the treatments of choice for patients with chronic fatigue syndrome.

In addition, the clinician's sympathetic listening and explanatory responses can help overcome the patient's frustrations and debilitation by this still mysterious illness. All patients should be encouraged to engage in normal activities to the extent possible and should be reassured that full recovery is eventually possible in most cases.

When to Refer

- Infections not responsive to standard treatment.
- Difficult to control hyperthyroidism or hypothyroidism.
- Severe psychological disease.
- Malignancy.

When to Admit

- Failure to thrive.
- Fatigue severe enough to impair activities of daily living.
- Fatigue combined with poor social support making it unlikely for patient to comply with medical therapy or reliably return for follow-up appointments.

Acute Headache

Essential Inquiries

- Age > 50 years.
- Rapid onset and severe intensity (ie, "thunderclap" headache).
- Fever.
- Trauma.
- Vision changes.
- HIV infection.
- Current or past history of hypertension.
- Neurologic findings (mental status changes, motor or sensory deficits).

General Considerations

Headache is a common reason that adults seek medical care, accounting for approximately 13 million visits each year in the United States to physicians' offices, urgent care clinics, and emergency departments. A broad range of disorders can cause headache. This chapter will deal only with the approach to a new acute headache—not due to trauma—in adolescents and adults. The challenge in the initial evaluation of acute headache is to identify which patients are presenting with an uncommon but life-threatening condition. In the emergency department setting, approximately 1% of patients seeking medical attention for acute headache will have a life-threatening condition, whereas the prevalence of life-threatening conditions in the office practice setting is considerably lower.

Regardless of the underlying cause, headache is currently believed to occur as a result of the release of neuropeptides from trigeminal nerve endings that encapsulate the blood vessels of the pia mater and dura mater, resulting in neurogenic inflammation. Because this represents a final common pathway for many etiologies, diminution of headache in response to typical migraine therapies (such as serotonin receptor antagonists or ketorolac) does not rule out critical conditions such as subarachnoid hemorrhage or meningitis as the underlying cause.

Clinical Findings

Symptoms

A careful history and physical examination should aim to identify causes of acute headache that require immediate treatment. These causes can be broadly classified as imminent or completed **vascular events** (intracranial hemorrhage, thrombosis, vasculitis, malignant hypertension, arterial dissection, or aneurysm), **infections** (abscess, encephalitis, meningitis), **intracranial masses** causing intracranial hypertension, **preeclampsia,** and **carbon monoxide poisoning.** Having the patient carefully describe the onset of headache can be helpful in diagnosing a serious cause. Report of a sudden-onset headache that reaches maximal and severe intensity within seconds or a few minutes is the classic description of a "thunderclap headache" and should precipitate workup for subarachnoid hemorrhage, since the estimated prevalence of subarachnoid hemorrhage in the setting of a thunderclap headache is 43%.

The general medical history can also guide the need for additional work-up. A new headache in a patient of advanced age or with a history of HIV disease under most circumstances (including a normal neurologic examination) warrants neuroimaging immediately (Table 2–11). When the patient has a medical history of hypertension—particularly uncontrolled hypertension—a complete search for criteria satisfying a diagnosis of "malignant hypertension" is appropriate to determine the correct urgency level of hypertension management (see Systemic Hypertension). Headache and hypertension associated with pregnancy may be due to preeclampsia. Episodic headache associated with the triad of hypertension, heart palpitations, and sweats is suggestive of pheochromocytoma. In the absence of thunderclap headache, advanced age, and HIV disease, a careful physical examination and detailed neurologic examination will usually determine acuity of the work-up and need for further diagnostic testing.

Table 2–11. Clinical features associated with acute headache that warrant urgent or emergent neuroimaging.
Prior to lumbar puncture
Abnormal neurologic examination
Abnormal mental status
Abnormal funduscopic examination (papilledema; loss of venous pulsations)
Meningeal signs
Emergent (conduct prior to leaving office or emergency department)
Abnormal neurologic examination
Abnormal mental status
Thunderclap headache
Urgent (scheduled prior to leaving office or emergency department)
HIV-positive patient[1]
Age > 50 years (normal neurologic examination)

[1] Use CT with or without contrast or MRI if HIV positive.

Adapted, with permission, from American College of Emergency Physicians. Clinical Policy: critical issues in the evaluation and management of patients presenting to the emergency department with acute headache. Ann Emerg Med. 2002 Jan;39(1):108–22.

Patient symptoms can also be useful for diagnosing migraine headache in the absence of the "classic" migraine pattern involving scintillating scotoma followed by unilateral headache, photophobia, and nausea and vomiting (Table 2–12). It is evident that the presence of three or more of these features can establish the diagnosis of migraine (in the absence of other clinical features that warrant neuroimaging studies), and the presence of none or one of these features (provided it is not nausea) can help to rule-out migraine.

Table 2–12. Summary likelihood ratios (LRs) for individual clinical features associated with migraine diagnosis.

Clinical Feature	**LR + (95% CI)**	**LR - (95% CI)**
Nausea	19 (15–25)	0.19 (0.18–0.20)

Photophobia	5.8 (5.1–6.6)	0.24 (0.23–0.26)
Phonophobia	5.2 (4.5–5.9)	0.38 (0.36–0.40)
Exacerbation by physical activity	3.7 (3.4–4.0)	0.24 (0.23–0.26)

Physical Examination

Critical components of the physical examination of the patient with acute headache include vital sign measurements, neurologic examination, and vision testing with funduscopic examination. The finding of fever with acute headache warrants additional maneuvers to elicit evidence of meningeal inflammation, such as Kernig and Brudzinski signs. Besides malignant hypertension, significant hypertension can also be a sign of intracranial hemorrhage, preeclampsia, and pheochromocytoma. Patients over 60 years of age should be examined for scalp or temporal artery tenderness.

Careful assessment of visual acuity, ocular gaze, visual fields, pupillary defects, the optic disk, and retinal vein pulsations is crucial. Diminished visual acuity is suggestive of glaucoma, temporal arteritis, or optic neuritis. Ophthalmoplegia or visual field defects may be signs of venous sinus thrombosis, tumor, or aneurysm. Afferent pupillary defects can be due to intracranial masses or optic neuritis. Ipsilateral ptosis and miosis suggest Horner syndrome and in conjunction with acute headache may signify carotid artery dissection. Finally, papilledema or absent retinal venous pulsations are signs of elevated intracranial pressure—findings that should be followed by neuroimaging prior to performing lumbar puncture (Table 2–11).

Mental status and complete neurologic evaluations are also critical and should include assessment of motor and sensory systems, reflexes, gait, cerebellar function, and pronator drift. Any abnormality on mental status or neurologic evaluation warrants emergent neuroimaging (Table 2–11).

Diagnostic Studies

Guidance on when to perform neuroimaging is summarized in Table 2–11. Under most circumstances, a noncontrast head CT is sufficient to exclude intracranial hypertension with impending herniation, intracranial hemorrhage, and many types of intracranial masses (notable exceptions include lymphoma and toxoplasmosis in HIV-positive patients, herpes simplex encephalitis and brain abscess). When appropriate, a contrast study can often be ordered to follow a normal noncontrast study. A normal neuroimaging study does not sufficiently exclude subarachnoid hemorrhage and should be followed by lumbar puncture. In patients for whom there is a high level of suspicion for subarachnoid hemorrhage or aneurysm, a normal CT and lumbar puncture should be followed by angiography within the next few days (provided the patient is medically stable). Lumbar puncture is also indicated to exclude infectious causes of acute headache, particularly in patients with fever or meningeal signs. Cerebrospinal fluid tests should routinely include Gram stain, white blood cell count with differential, red blood cell count, glucose, total protein, and bacterial culture. In appropriate patients, also consider testing cerebrospinal fluid for VDRL (syphilis), cryptococcal antigen (HIV-positive patients), acid-fast bacillus stain and culture, and complement fixation and culture for coccidioidomycosis. Storage of an extra tube with 5 mL of cerebrospinal fluid is also prudent for conducting unanticipated tests in the immediate future. Consultation with infectious disease experts regarding local availability of newer polymerase chain reaction tests for specific infectious pathogens (eg, herpes simplex 2) should also be considered in patients with evidence of central nervous system infection but no identifiable pathogen.

In addition to neuroimaging and lumbar puncture, additional diagnostic tests for exclusion of life-threatening causes of acute headache include erythrocyte sedimentation rate (temporal arteritis; endocarditis), urinalysis (malignant hypertension; preeclampsia), and sinus CT or radiograph (bacterial sinusitis, independently or as a cause of venous sinus thrombosis).

Treatment

Treatment should be directed at the cause of acute headache. In patients in whom migraine or migraine-like headache has been diagnosed, early treatment with NSAIDs or triptans can often abort or provide significant relief of symptoms. The effectiveness of NSAIDs and triptans appears to be equivalent, although combination sumatriptan-naproxen appears to provide a greater sustained response (2–24 hours) compared with monotherapy with either agent alone. Nonoral medication administration is often necessary for patients with significant nausea and vomiting, in which case nasal and subcutaneous triptans and intramuscular ketorolac are therapeutic options. Other causes of acute headache, such as subarachnoid hemorrhage, intracranial mass, or meningitis, usually require emergent treatment in the hospital.

When to Refer

- Frequent migraines not responsive to standard therapy.
- Migraines with atypical features.
- Chronic daily headaches due to medication overuse.

When to Admit

- Need for repeated doses of parenteral pain medication.
- To facilitate an expedited work-up requiring a sequence of procedures and neuroimaging.
- Monitoring for progression of symptoms and neurologic consultation when the initial emergency department work-up is inconclusive.
- Pain severe enough to impair activities of daily living or limit participation in follow-up appointments or consultation.

Dysuria

Essential Inquiries

- Fever.
- Nausea or vomiting.
- New back or flank pain.
- Vaginal discharge.
- Pregnancy risk.
- Structural abnormalities.
- Instrumentation of urethra or bladder.

General Considerations

Dysuria (painful urination) is a common reason for adolescents and adults to seek urgent medical attention. An inflammatory process (eg, infection; autoimmune disorder) underlies most causes of dysuria. In women, cystitis will be diagnosed in up to 50–60% of cases, and has an incidence of 0.5–0.7% per year in sexually active young women. The key objective in evaluating women with dysuria is to exclude serious upper urinary tract disease, such as acute pyelonephritis, and sexually transmitted diseases. In contrast, in men, urethritis accounts for the vast majority of cases of dysuria.

Clinical Findings

Symptoms

Well-designed cohort studies have shown that some women can be reliably diagnosed with uncomplicated cystitis without a physical examination or urinalysis, and randomized controlled trials show that telephone management of uncomplicated cystitis is safe and effective. An increased likelihood of cystitis is present when women report multiple irritative voiding symptoms (dysuria, urgency, frequency), fever, or back pain (likelihood ratios = 1.6–2.0). Inquiring about symptoms of vulvovaginitis is imperative, since the presence of vaginal discharge or itching substantially decreases the likelihood of cystitis (likelihood ratios = 0.2–0.3). When women report dysuria and urinary frequency, and deny vaginal discharge and irritation, the likelihood ratio for culture-confirmed cystitis is 24.5. In contrast, when vaginal discharge or irritation is present, as well as dysuria or urinary frequency, the likelihood ratio is 0.7. Gross hematuria in women with voiding symptoms usually represents hemorrhagic cystitis, but can also be a sign of bladder cancer (particularly in older patients) or upper tract disease. Failure of hematuria to resolve with antibiotic treatment should prompt further evaluation of the bladder and kidneys. Chlamydial infection should be strongly considered among women age 25 years or younger who are sexually active and seeking medical attention for a suspected urinary tract infection for the first time or have a new partner.

Because fever and back pain, as well as nausea and vomiting, are considered harbingers of (or clinical criteria for) acute pyelonephritis, women with these symptoms should usually be examined by a clinician prior to treatment in order to exclude coexistent urosepsis, hydronephrosis, or nephrolithiasis. Other major risk factors for acute pyelonephritis (among women 18–49 years of age) relate to sexual behaviors (frequency of sexual intercourse three or more times per week, new sexual partner in previous year, recent spermicide use), as well as diabetes mellitus and recent urinary tract infection or incontinence. Finally, pregnancy risk, underlying structural factors (polycystic kidney disease, nephrolithiasis, neurogenic bladder), immunosuppression, diabetes, and a history of recent bladder or urethral instrumentation usually alter the treatment regimen (antibiotic choice, duration of treatment, or both) of uncomplicated cystitis.

Physical Examination

The presence of fever, tachycardia, or hypotension should alert the clinician to the possibility of urosepsis and the potential need for hospitalization. A focused examination in women, in uncomplicated circumstances, could be limited to ascertainment of costovertebral angle tenderness and to a lower abdominal and pelvic examination, if the history suggests vulvovaginitis or cervicitis.

Diagnostic Studies

Urinalysis

Urinalysis is probably overutilized in the evaluation of dysuria. The probability of culture-confirmed urinary tract infection among women with a history and physical examination compatible with uncomplicated cystitis is about 70–90%. Urinalysis is most helpful when the woman with dysuria does not have other typical features of cystitis. Dipstick detection (> trace) of leukocytes, nitrites, or blood supports a diagnosis of cystitis. When both leukocyte and nitrite tests are positive, the likelihood ratio is 4.2, and when both are negative, the likelihood ratio is 0.3. The negative predictive value of urinalysis is not sufficient to exclude culture-confirmed urinary tract infection in women with multiple and typical symptoms; and randomized trial evidence shows that antibiotic treatment is beneficial to women with typical symptoms and negative urinalysis dipstick tests.

Urine Culture

Urine culture should be considered for all women with upper tract symptoms (prior to initiating antibiotic therapy), as well as those with dysuria and a negative urine dipstick test. In symptomatic women, a clean-catch urine culture is considered positive when 10^2–10^3 colony-forming units/mL of a uropathogenic organism is detected.

Renal Imaging

When severe flank or back pain is present, the possibility of complicated kidney infection (perinephric abscess, nephrolithiasis) or of hydronephrosis should be considered. Depending on local availability, acceptable imaging options to assess for hydronephrosis include abdominal radiographs, renal ultrasound, or CT scanning. To exclude nephrolithiasis, noncontrast helical CT scanning is more accurate than intravenous urography and is rapidly becoming the diagnostic test of choice for this purpose. In a meta-analysis, the positive and negative likelihood ratios of helical CT scanning for diagnosis of nephrolithiasis were 23.2 and 0.05, respectively.

Differential Diagnosis

The differential diagnosis of dysuria in women includes acute cystitis, acute pyelonephritis, vaginitis (*Candida*, bacterial vaginosis, *Trichomonas*, herpes simplex), urethritis/cervicitis (*Chlamydia*, gonorrhea), and interstitial cystitis/painful bladder syndrome. Nucleic acid amplification tests from first-void urine or vaginal swab specimens are highly sensitive for detecting chlamydial infection.

Treatment

Definitive treatment is directed to the underlying cause of the dysuria. An evidence-informed algorithm for managing suspected urinary tract infection in women is shown in Figure 2–3: illustration. This algorithm supports antibiotic treatment of most women with multiple and typical symptoms of urinary tract infection without performing urinalysis or urine culture. Symptomatic relief can be provided with phenazopyridine, a urinary analgesic that is available over-the-counter; it is used in combination with antibiotic therapy (when a urinary tract infection has been confirmed) but for no more than 2 days. Patients should be informed that phenazopyridine will cause orange/red discoloration of their urine and other bodily fluids (eg, some contact lens wearers have reported discoloration of their lenses). Rare cases of methemoglobinemia and hemolytic anemia have been reported, usually with overdoses or underlying renal dysfunction.

Figure 2–3

Proposed algorithm for evaluating women with symptoms of acute urinary tract infection (UTI). (Modified and reproduced, with permission, from Bent S et al. Does this woman have an acute uncomplicated urinary tract infection? JAMA. 2002 May 22–29;287(20):2701–10.)

In cases of interstitial cystitis/painful bladder syndrome, patients will often respond to a multimodal approach that may include urethral/vesicular dilation, biofeedback, cognitive behavioral therapy, antidepressants, dietary changes, vaginal emollients, and other supportive measures.

When to Refer

- Anatomic abnormalities leading to repeated urinary infections.
- Infections associated with nephrolithiasis.
- Persistent interstitial cystitis/painful bladder syndrome.

When to Admit

- Severe pain requiring parenteral medication or impairing ambulation or urination (such as severe primary herpes simplex genitalis).

- Dysuria associated with urinary retention or obstruction.

Preoperative Evaluation: Introduction

Each year, tens of millions of patients in the United States undergo a surgical procedure requiring general or spinal-epidural anesthesia. An increasing number of these patients are over age 65. Recent estimates suggest that 15–23% of Americans over the age of 65 undergo surgery in any given year. Operative mortality and morbidity have declined over the past 10–20 years due to improvements in surgical, anesthetic, and monitoring techniques. The rate of major complications varies from less than 1% to nearly 20% depending on the presence of underlying disease, the type of surgery, and to a lesser extent, the patient's age. In patients over 70 years of age, the occurrence of a postoperative complication is associated with decreased long-term functional status and survival. Cardiac, pulmonary, infectious, and neurologic complications account for most of the perioperative morbidity and mortality. The traditional roles of the medical consultant include evaluating the severity and stability of the patient's medical conditions, providing a surgical risk assessment, and recommending measures to reduce the risk of perioperative complications. In addition, hospitalists sometimes directly manage the medical aspects of patients' postoperative care. These comanagement arrangements have generally increased provider satisfaction compared to traditional medical consultation but have not yet been proven to reduce the risk of major complications.

Physiologic Effects of Anesthesia & Surgery

In general, decisions about anesthetic techniques and agents, intraoperative monitoring, and other aspects of care within the operating room should be left to the anesthesiologist. However, it is important for the medical consultant to understand the physiologic effects of anesthesia and surgery. Both general and regional (spinal or epidural) anesthetic agents usually cause peripheral vasodilation, and most of the commonly used general anesthetic regimens also decrease myocardial contractility. These effects often result in transient mild hypotension or, less frequently, prolonged or more severe hypotension. The decrease in tidal volume and functional residual capacity caused by general and regional anesthesia can close small airways and lead to atelectasis. Epinephrine, norepinephrine, and cortisol levels increase during surgery and remain elevated for 1–3 days. Serum antidiuretic hormone levels may be elevated for up to 1 week postoperatively, which can lead to hyponatremia. Anesthesia and surgery may be associated with relative hypercoagulable and inflammatory states mediated by increases in plasminogen activator-1, factor VIII, and platelet reactivity, and increased levels of tumor necrosis factor, interleukins 1 and 6, and C-reactive protein. These effects may be less evident with spinal or epidural anesthesia compared with general anesthesia. The degree to which these hypercoagulable or inflammatory states contribute to perioperative morbidity is not known.

There is no definitive evidence that regional anesthesia is preferable to general anesthesia in terms of overall surgical outcomes in large clinical trials. However, subgroup analyses in patients undergoing thoracic, abdominal, and vascular surgery have consistently demonstrated superior analgesia in the regional anesthesia group and a reduction in specific adverse outcomes (cardiac, pulmonary, or neurologic). Similarly, routine use of invasive hemodynamic monitoring with pulmonary artery catheters did not improve outcomes in a large randomized trial. Two randomized trials have shown a reduction in postoperative cardiac outcomes through the maintenance of normothermia during the perioperative period.

Evaluation of the Asymptomatic Patient

Patients without significant medical problems—especially those under age 50—are at very low risk for perioperative complications. Their preoperative evaluation should include a complete history and physical examination. Special emphasis is placed on the assessment of functional status, exercise tolerance, and cardiopulmonary symptoms and signs in an effort to reveal previously unrecognized disease (especially cardiopulmonary disease) that may require further evaluation prior to surgery. In addition, a directed bleeding history (Table 3–1) should be taken to uncover coagulopathies that could contribute to excessive surgical blood loss. Routine preoperative testing of asymptomatic healthy patients under age 50 has not been found to help predict or prevent complications.

Table 3–1. Findings suggestive of a bleeding disorder.
Unprovoked bruising on the trunk of > 5 cm in diameter
Frequent unprovoked epistaxis or gingival bleeding
Menorrhagia with iron deficiency
Hemarthrosis with mild trauma
Prior excessive surgical blood loss or reoperation for bleeding
Family history of abnormal bleeding
Presence of severe kidney or liver disease

Patients who are older than 50 years and those with risk factors for coronary artery disease should have a 12-lead ECG because evidence of clinically silent coronary artery disease should prompt further cardiac evaluation. Minor ECG abnormalities such as bundle branch block, T wave changes, and premature ventricular contractions do not predict adverse postoperative outcomes. Of note, patients undergoing minor or minimally invasive procedures (such as cataract surgery) may not require any routine preoperative tests.

Although preoperative evaluation has focused primarily on organ system diseases that increase the risk of perioperative complications, there is growing recognition of the importance of addressing long-term behavioral medicine issues such as depression and tobacco addiction. One survey found that depression was more common in a presurgical population than in the general community. The preoperative period may also be an optimal time to initiate smoking cessation efforts. A systematic review found that smoking cessation programs started in a preoperative evaluation clinic increased the odds of abstinence at 3–6 months by nearly 60%.

Cardiac Risk Assessment & Reduction

Cardiac complications of noncardiac surgery are a major cause of perioperative morbidity and mortality. The most important perioperative cardiac complications are myocardial infarction (MI) and cardiac death. Other complications include congestive heart failure (CHF), arrhythmias, and unstable angina. The principal patient-specific risk factor is the presence of end-organ cardiovascular disease. This includes not only coronary artery disease and CHF, but also cerebrovascular disease and chronic renal insufficiency. Diabetes mellitus is treated as a cardiovascular disease equivalent and has also been shown to increase the risk of cardiac complications. Major abdominal, thoracic, and vascular surgical procedures (especially abdominal aortic aneurysm repair) carry a higher risk of postoperative cardiac complications, likely due to their associated major fluid shifts, hemorrhage, and hypoxemia. These risk factors were identified in a validated multifactorial risk prediction index: the Revised Cardiac Risk Index (Table 3–2). The Revised Cardiac Risk Index has become a widely used tool for assessing and communicating cardiac risk and has been incorporated into routine perioperative care guidelines. Severely limited exercise capacity and greater severity of cardiac symptoms also predict higher cardiac risk. Emergency operations are also associated with greater cardiac risk. However, emergency operations should not be delayed by extensive cardiac evaluation. Instead, patients facing emergency surgery should be medically optimized for surgery as quickly as possible and closely monitored for cardiac complications during the perioperative period.

Table 3–2. Revised Cardiac Risk Index.

Independent Predictors of Postoperative Cardiac Complications	
1. Intrathoracic, intraperitoneal, or infrainguinal vascular surgery	
2. History of ischemic heart disease	
3. History of congestive heart failure	
4. Insulin treatment for diabetes mellitus	
5. Serum creatinine level > 2 mg/dL	
6. History of cerebrovascular disease	
Scoring (Number of Predictors Present)	**Risk of Major Cardiac Complications[1]**
None	0.4%
One	0.9%
Two	7.0%
More than two	11%

[1] Myocardial infarction, pulmonary edema, ventricular fibrillation, cardiac arrest, and complete heart block.

Adapted, with permission, from Lee TH et al. Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. Circulation. 1999 Sep 7;100(10):1043–9.

Recent studies have found that measurement of B-type natriuretic peptide (BNP) level may be a useful tool for preoperative cardiac risk assessment. The sensitivity and specificity of an elevated BNP level for predicting complications was at least as good as those of multifactorial risk indices and noninvasive stress testing. Studies differed, however, in their definition of an elevated BNP level. The appropriate role of measuring BNP level in a preoperative evaluation has yet to be determined.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Role of Preoperative Noninvasive Ischemia Testing

Candidates for noninvasive ischemia testing independent of the planned noncardiac surgery should generally have such testing prior to elective surgery. Conversely, stress testing should be omitted if the results will not alter management.

Most patients can be accurately risk-stratified by history, physical examination, and electrocardiogram (ECG). Patients without clinical predictors for cardiac complications (Table 3–2) or who have at least fair functional capacity are at low risk for cardiac complications. Noninvasive testing in these patients is generally not helpful. Patients with more severe cardiac symptoms, such as New York Heart Association class III or IV angina (see Chapter 10: Heart Disease), poor functional capacity, or a high Revised Cardiac Risk Index score are much more likely to suffer cardiac complications. Stress testing of these patients may be able to stratify them into low-risk and high-risk subgroups, particularly when major vascular surgery is planned. For patients who will undergo vascular surgery and who have multiple Revised Cardiac Risk Index predictors, the absence of inducible ischemia or the presence of only mild, limited ischemia on dipyridamole scintigraphy or dobutamine stress echocardiography predicts a generally acceptable risk of perioperative cardiac death or MI. In contrast, extensive inducible ischemia in this population predicts a very high risk of cardiac complications, which may not be modifiable by either medical management or coronary revascularization. An approach to perioperative cardiac risk assessment and management in patients with known or suspected stable coronary artery disease is shown in Figure 3–1: illustration.

Figure 3–1
Assessment and management of patients with known or suspected stable coronary artery disease (CAD) undergoing elective major noncardiac surgery. (OR, operating room.)

Perioperative Management of Patients with Coronary Artery Disease

Patients with acute coronary syndromes are at extremely high risk for complications and require immediate management of their cardiac disease prior to any preoperative evaluation (see Chapter 10: Heart Disease). Patients with stable coronary artery disease have a 1–5% risk of MI and about a 1% mortality rate. In some patients, preoperative cardioprotective strategies can minimize these risks. Postoperative myocardial ischemia or infarction often presents atypically or may be asymptomatic. Symptoms and signs that should prompt consideration of postoperative MI include unexplained hypotension, hypoxemia, or delirium. However, current evidence is insufficient to formulate specific recommendations for screening asymptomatic patients for ischemia through the use of ECG or cardiac enzyme monitoring.

Medications

Preoperative antianginal medications, including -blockers, calcium channel blockers, and nitrates, should be continued preoperatively and during the postoperative period. Early, small clinical trials demonstrated a reduction in perioperative cardiac morbidity and mortality with prophylactic -blocking agents. A randomized trial in vascular surgery patients with ischemia on dobutamine stress echocardiography found that bisoprolol reduced the 30-day risk of cardiac mortality or nonfatal MI from 34% to 3% in these high-risk patients. In contrast, subsequent trials found a much smaller cardioprotective effect of -blockers in lower risk patients. In the largest of these studies, extended-released metoprolol reduced the absolute risk of cardiac complications by only 1.1% in patients with at least one Revised Cardiac Risk Index predictor who were undergoing major surgery. This was offset, however, by a 0.8% absolute increase in total mortality. Hypotension and bradycardia were more common when patients received -blockers; in addition, the risk of stroke was higher in these patients. Because of the uncertain benefit-to-risk ratio of perioperative -blockade, it should be reserved for patients with a relatively high risk of cardiac complications. Suggested indications for prophylactic -blockade are presented in Table 3–3. Comparative trials between different -blockers are lacking, although all cardioselective agents (eg, metoprolol or atenolol) are believed to be equivalent. The dose should be adjusted to maintain a heart rate under 65 beats per minute. Ideally, -blockers should be started well in advance of surgery, to allow time to gradually titrate up the dose without causing excessive bradycardia or hypotension. -blockers should be continued for at least 3–7 days after surgery.

Table 3–3. Indications for prophylactic perioperative -blockade.

Strong indications	Patient already taking -blocker to treat ischemia, arrhythmia, or hypertensionPatient with potential for myocardial ischemia (eg, reversibility on stress test) undergoing major vascular surgery
Possible indications	Patients with potential for myocardial ischemia undergoing major nonvascular surgeryPatient with coronary disease or multiple other clinical predictors (heart

	failure, chronic kidney disease, diabetes mellitus) undergoing any major surgery

A meta-analysis of six randomized trials that studied the use of prophylactic $_2$-agonists, such as clonidine or mivazerol, showed that perioperative cardiac mortality was reduced in vascular surgery patients. In a subsequent randomized trial, patients received either clonidine (0.2 mg/d orally or via transdermal patch) or placebo for 4 days beginning the night before a variety of noncardiac procedures. Although there was no effect on perioperative outcomes, the 2-year mortality in the clonidine group was 15%, compared with 29% in the placebo group. Based on these data, $_2$-agonists should be considered in high-risk patients undergoing vascular surgery who are unable to take -blocking agents.

Observational studies show an association between the use of HMG-CoA reductase inhibitors (statins) during the perioperative period and lower rates of mortality and postoperative MI. A randomized trial in statin-naïve patients undergoing vascular surgery found that extended-release fluvastatin reduced the 30-day risk of cardiac death or nonfatal MI from 10.1% to 4.8%. Although there are insufficient data to make a strong recommendation regarding the perioperative use of prophylactic statins, they should be considered in patients undergoing vascular surgery and other patients deemed to be at high risk for cardiac complications. Patients already taking statins should continue these agents during the perioperative period.

Coronary Revascularization

Retrospective studies suggest that patients who had previously undergone coronary artery bypass grafting (CABG) surgery or percutaneous coronary interventions (PCI) have a relatively low risk of cardiac complications when undergoing subsequent noncardiac surgery. However, one trial randomized over 500 patients with angiographically proven coronary artery disease to either coronary revascularization (with either CABG or PCI) or medical management alone before vascular surgery. Postoperative nonfatal MI, 30-day mortality, and long-term mortality did not differ, suggesting that prophylactic revascularization before noncardiac surgery does not prevent cardiac complications. Thus, current data argue that preoperative CABG or PCI should only be performed on patients who have indications for the procedure independent of the planned noncardiac operation. In patients who have undergone recent intracoronary stenting, observational studies suggest that perioperative cardiac mortality rate may be very high if antiplatelet therapy is stopped due to concern for surgical site bleeding. The presumed mechanism of this increased mortality is acute stent thrombosis that results from premature discontinuation of antiplatelet therapy. Therefore, elective surgery should be deferred for at least 1 month after placement of a bare-metal stent and for a year after placement of a drug-eluting stent if antiplatelet therapy must be stopped perioperatively.

CHF & Left Ventricular Dysfunction

An estimated one-third of perioperative cardiac deaths result from CHF. Decompensated CHF, manifested by an elevated jugular venous pressure, an audible third heart sound, or evidence of pulmonary edema on physical examination or chest radiography, significantly increases the risk of perioperative pulmonary edema (roughly 15%) and cardiac death (2–10%). Elective surgery should be postponed in patients with decompensated CHF until it can be brought under control.

Patients with compensated left ventricular dysfunction are at increased risk for perioperative pulmonary edema. One large study found that patients with a left ventricular ejection fraction of less than 50% had an absolute risk of 12% for postoperative CHF compared with 3% for patients with an ejection fraction greater than 50%. Such patients should continue taking all medications for chronic heart failure up to the day of surgery. Patients receiving digoxin and diuretics should have serum electrolyte and digoxin levels measured prior to surgery because abnormalities in these levels may increase the risk of perioperative arrhythmias. Clinicians must be cautious not to give too much diuretic, since the volume-depleted patient will be much more susceptible to intraoperative hypotension. Preoperative echocardiography or radionuclide angiography to assess left ventricular function should be considered when there is suspicion of left ventricular dysfunction and when the cause of left ventricular dysfunction is in question. The surgeon and anesthesiologist should be made aware of the presence and severity of left ventricular dysfunction so that appropriate decisions can be made regarding perioperative fluid management and intraoperative monitoring.

Valvular Heart Disease

There are few data available regarding the perioperative risks of valvular heart disease for noncardiac surgery independent of associated coronary artery disease or CHF. The severity of valvular lesions should be evaluated by echocardiography or cardiac catheterization before noncardiac surgery to allow for appropriate fluid management and consideration of invasive intraoperative monitoring. Patients with severe symptomatic aortic stenosis are clearly at increased risk for cardiac complications and should not undergo elective surgery. In a series of patients with aortic stenosis who underwent noncardiac surgery, death or nonfatal MI occurred in 31%

in patients with severe aortic stenosis (aortic valve area < $0.7\ cm^2$), in 11% in those with moderate aortic stenosis (aortic valve area $0.7–1.0\ cm^2$), and in 2% in those without aortic stenosis. Other studies have found that patients with asymptomatic aortic stenosis appeared to be at lower risk than patients with symptomatic aortic stenosis. Patients with mitral stenosis require heart rate control to maintain diastolic filling time. Patients with aortic or mitral regurgitation likely benefit from afterload reduction and careful attention to volume status. Candidates for valve replacement surgery or balloon valvuloplasty (if only short-term relief is needed) independent of the planned noncardiac surgery should have the valve correction procedure performed first.

Arrhythmias

The finding of a rhythm disturbance on preoperative evaluation should prompt consideration of further cardiac evaluation, particularly when the finding of structural heart disease would alter perioperative management. Patients with a rhythm disturbance without evidence of underlying heart disease are at low risk for perioperative cardiac complications.

Management of patients with arrhythmias in the preoperative period should be guided by factors independent of the planned surgery. In patients with atrial fibrillation, adequate rate control should be established.

Symptomatic supraventricular and ventricular tachycardia must be controlled prior to surgery. There is no evidence that the use of antiarrhythmic medications to suppress an asymptomatic arrhythmia alters perioperative risk.

Patients who have indications for a permanent pacemaker should have it placed prior to noncardiac surgery. When surgery is urgent, these patients may be managed perioperatively with temporary transvenous pacing. Patients with bundle branch block who do not meet recognized criteria for a permanent pacemaker do not require pacing during surgery. The anesthesiologist must be notified that a patient has an implanted pacemaker or defibrillator so that steps may be taken to prevent device malfunction caused by electromagnetic interference from the intraoperative use of electrocautery.

Hypertension

Mild to moderate hypertension is associated with intraoperative blood pressure lability and asymptomatic myocardial ischemia but does not appear to be an independent risk factor for cardiac complications. No evidence supports delaying surgery in order to better control mild to moderate hypertension. Medications for chronic hypertension should generally be continued up to and including the day of surgery. Consideration should be given to holding angiotensin-converting enzyme inhibitors and angiotensin receptor blockers on the day of surgery, as these agents may increase the risk of intraoperative hypotension.

Severe hypertension, defined as a systolic pressure greater than 180 mm Hg or diastolic pressure greater than 110 mm Hg, appears to be an independent predictor of perioperative cardiac complications, including MI and CHF. It seems wise to delay surgery in patients with severe hypertension until blood pressure can be controlled, although it is not known whether the risk of cardiac complications is reduced with this approach.

Pulmonary Evaluation in Non–Lung Resection Surgery

Pneumonia and respiratory failure requiring prolonged mechanical ventilation are the most important postoperative pulmonary complications and occur in 2–19% of surgical procedures. The occurrence of a postoperative pulmonary complication has been associated with a significant increase in hospital length of stay.

Risk Factors for the Development of Postoperative Pulmonary Complications

The risk of developing a pulmonary complication is highest in patients undergoing cardiac, thoracic, and upper abdominal surgery, with reported complication rates ranging from 9% to 19%. The risk in patients undergoing lower abdominal or pelvic procedures ranges from 2% to 5%, and for extremity procedures the range is less than 1–3%. The pulmonary complication rate for laparoscopic procedures appears to be much lower than that for open procedures. In one series of over 1500 patients who underwent laparoscopic cholecystectomy, the pulmonary complication rate was less than 1%. Other procedure-related risk factors include prolonged anesthesia time, need for general anesthesia, and emergency operations.

Among the many patient-specific risk factors for postoperative pulmonary complications, the strongest predictor appears to be advanced age. A meta-analysis found that surgical patients in their seventh decade had a fourfold higher risk of pulmonary complications compared with patients under age 50. Patients with chronic obstructive pulmonary disease (COPD) or CHF have at least twice the risk compared with patients without these conditions. In a single large prospective cohort of US military veterans, additional clinical risk factors for the development of postoperative pneumonia included dependent functional status, impaired sensorium, and prior stroke, long-term corticosteroid use, heavy alcohol consumption, and current cigarette smoking. In another study, cigarette smoking was also found to double the risk of postoperative pneumonia, even when controlling for underlying lung disease.

Patients with asthma are at increased risk for bronchospasm during tracheal intubation and extubation and during the postoperative period. However, if patients are at their optimal pulmonary function (as determined by symptoms, physical examination, or peak flow rate) at the time of surgery, they are not at increased risk for other pulmonary complications. Mild or moderate obesity also does not appear to increase the risk of clinically important pulmonary complications, but postoperative pneumonia was found to be twice as likely to develop in morbidly obese patients—those weighing over 113 kg (250 lb)—than in patients weighing less. Obese patients are prone to obstructive sleep apnea. This condition has been associated with a variety of postoperative complications, particularly in patients undergoing bariatric surgery. A summary of risk factors for pulmonary complications is presented in Table 3–4.

Table 3–4. Clinical risk factors for postoperative pulmonary complications.
Upper abdominal or cardiothoracic surgery
Prolonged anesthesia time (> 4 hours)
Age > 60 years
Chronic obstructive pulmonary disease
Congestive heart failure
Tobacco use (> 20 pack-years)
Impaired cognition or sensorium
Functional dependency or prior stroke
Morbid obesity
Low serum albumin level
Obstructive sleep apnea

Pulmonary Function Testing & Laboratory Studies

Most studies have shown that preoperative pulmonary function testing (PFT) in unselected patients is not helpful in predicting postoperative pulmonary complications. The data are conflicting regarding the usefulness of preoperative PFT in certain selected groups of patients, such as the morbidly obese or those with COPD, especially when undergoing upper abdominal or cardiothoracic surgery. Assessment of the severity of COPD using PFT has not been shown to improve upon the clinical risk assessment with the exception that patients with a forced expiratory volume in 1 second (FEV_1) under 500 mL or an FEV_1 below 50% of the predicted value appear to be at particularly high risk. However, there is no clear degree of PFT abnormality that can be used as an absolute contraindication to non–lung resection surgery. Definitive recommendations regarding the indications for preoperative PFT cannot be made. In general terms, such testing may be helpful to confirm the diagnosis of COPD or asthma, to assess the severity of known pulmonary disease, and perhaps as part of the risk assessment for patients undergoing upper abdominal, cardiac, or thoracic surgery. Some experts have also advocated polysomnography to diagnose obstructive sleep apnea prior to bariatric surgery, but the benefits of this approach are unproven. Abnormally low or high blood urea nitrogen levels (indicating malnutrition and renal insufficiency, respectively) have been found to predict postoperative pulmonary complications. In addition, several studies have found that a low serum albumin level is associated with a higher risk of pulmonary complications and a higher overall mortality.

Arterial blood gas measurement is not routinely recommended except in patients with known lung disease and suspected hypoxemia or hypercapnia.

Perioperative Management

Retrospective studies have shown that smoking cessation reduced the incidence of pulmonary complications, but only if it was initiated at least 1–2 months before surgery. The incidence of postoperative pulmonary complications in patients with COPD or asthma may be reduced by preoperative optimization of pulmonary function. Patients who are wheezing will probably benefit from preoperative therapy with bronchodilators and, in certain cases, corticosteroids. Antibiotics may be beneficial for patients who cough with purulent sputum if the sputum can be cleared before surgery. On the other hand, the use of antibiotics in unselected patients undergoing head and neck cancer surgery did not reduce the occurrence of pulmonary complications. Patients receiving oral theophylline should continue taking the drug perioperatively. A serum theophylline level should be measured to rule out toxicity. Most patients with COPD can be treated with cardioselective -blockers if indicated to prevent perioperative cardiac complications without suffering respiratory compromise.

Postoperative risk reduction strategies have centered on promoting lung expansion through the use of incentive spirometry, continuous positive airway pressure (CPAP), intermittent positive-pressure breathing (IPPB), and deep breathing exercises. Although trial results have been mixed, all these techniques have been shown to reduce the incidence of postoperative atelectasis and, in a few studies, to reduce the incidence of postoperative pulmonary complications. In most comparative trials, these methods were equally effective. Given the higher cost of CPAP and IPPB, incentive spirometry and deep breathing exercises are the preferred methods for most patients. However, in a randomized trial of patients undergoing esophageal or gastric resection, CPAP was more effective at preventing respiratory failure than incentive spirometry or deep breathing exercises and thus may be preferable after these operations. Incentive spirometry must be performed for 15 minutes every 2 hours. Deep breathing exercises must be performed hourly and consist of 3-second breath-holding, pursed lip breathing, and coughing. These measures should be started preoperatively and be continued for 1–2 days postoperatively.

A single-blind, randomized trial found that an intensive preoperative inspiratory muscle training program reduced the risk of postoperative pneumonia from 16% to 6.5% in patients undergoing coronary bypass surgery. Similar trials in patients undergoing upper abdominal surgery have shown that preoperative inspiratory muscle training reduces the incidence of atelectasis. Preoperative inspiratory muscle training consists of using incentive spirometry and forced expiration maneuvers daily for at least 20 minutes and beginning at least 2 weeks prior to surgery. In addition, a respiratory therapist evaluates and coaches the patient weekly. If available, it is reasonable to refer high-risk patients undergoing cardiac, thoracic, or upper abdominal surgery to perform inspiratory muscle training for 2 or more weeks preoperatively.

Finally, limiting the use of nasogastric decompression tubes after abdominal surgery to only those patients who have specific indications (such as postoperative ileus) has been shown to reduce pulmonary complications.

Evaluation of the Patient with Liver Disease

Patients with serious liver disease are at increased risk for perioperative morbidity and demise. Appropriate preoperative evaluation requires consideration of the effects of anesthesia and surgery on postoperative liver function and of the complications associated with anesthesia and surgery in patients with preexisting liver disease.

The Effects of Anesthesia & Surgery on Liver Function

Postoperative elevation of serum aminotransferase levels is a relatively common finding after major surgery. Most of these elevations are transient and not associated with hepatic dysfunction. Studies in the 1960s and early 1970s showed that patients with liver disease are at increased relative risk for postoperative deterioration in hepatic function, although the absolute risk is not known. General anesthetic agents may cause deterioration of hepatic function via intraoperative reduction in hepatic blood flow leading to ischemic injury. Medications used for regional anesthesia produce similar reductions in hepatic blood flow and thus may be equally likely to lead to ischemic liver injury. Intraoperative hypotension, hemorrhage, and hypoxemia may also contribute to liver injury.

Risk Factors for Surgical Complications

Observational studies have found that surgery in patients with serious liver disease is associated with a variety of complications, including hemorrhage, infection, renal failure, and encephalopathy, and with a substantial mortality rate. A key limitation in interpreting these data is our inability to determine the contribution of the liver disease to the observed complications independent of the surgical procedure.

Acute hepatitis appears to increase surgical risk. In three small series of patients with acute viral hepatitis who underwent abdominal surgery, the mortality rate was roughly 10%. Cirrhotic patients undergoing portosystemic shunt surgery who have evidence of alcoholic hepatitis on the preoperative liver biopsy also have a significantly increased surgical mortality rate compared with patients without alcoholic hepatitis. It seems reasonable to delay elective surgery in patients with acute viral or alcoholic hepatitis until the acute episode has resolved. These data are not sufficient to warrant substantial delays in urgent or emergent surgery.

There are few data regarding the risks of surgery in patients with chronic hepatitis. In a series of 272 patients with chronic hepatitis undergoing a variety of surgical procedures for variceal hemorrhage, the in-hospital mortality rate was less than 2%. Patients with serum aminotransferase levels greater than 150 units/L were excluded from this analysis. In a study of patients undergoing hepatectomy for hepatocellular carcinoma, patients with both cirrhosis and active hepatitis on the preoperative liver biopsy had a fourfold increase in mortality (8.7%) compared with patients with cirrhosis alone or active hepatitis alone. In a study of patients with chronic viral hepatitis who underwent liver resection for cancer, a preoperative hyaluronic acid level greater than 200 ng/mL was associated with a substantially increased risk of postoperative hepatic failure.

In patients with cirrhosis, postoperative complication rates correlate with the severity of liver dysfunction. Traditionally, severity of dysfunction has been assessed with the Child-Turcotte-Pugh score (see Chapter 16: Liver, Biliary Tract, & Pancreas Disorders). Patients with Child-Turcotte-Pugh class C cirrhosis who underwent portosystemic shunt surgery, biliary surgery, or trauma surgery during the 1970s and 1980s had a 50–85% mortality rate. Patients with Child-Turcotte-Pugh class A or B cirrhosis who underwent abdominal surgery during the 1990s, however, had relatively low mortality rates (hepatectomy 0–8%, open cholecystectomy 0–1%, laparoscopic cholecystectomy 0–1%). A recent multivariate analysis found that the Model for End-stage Liver Disease (MELD) score (which incorporates bilirubin and creatinine levels, and the prothrombin time expressed as the International Normalized Ratio) was the strongest predictor of postoperative mortality and outperformed the Child-Turcotte-Pugh classification. Patients with a MELD score above the median score of 8 had a 30-day mortality risk exceeding 10%. A conservative approach would be to avoid elective surgery in patients with Child-Turcotte-Pugh class C cirrhosis or in patients with a MELD score greater than 8. In addition, when surgery is elective, it is prudent to attempt to reduce the severity of ascites, encephalopathy, and coagulopathy preoperatively.

Preoperative Hematologic Evaluation

Three of the more common clinical situations faced by the medical consultant are the patient with preexisting anemia, the assessment of bleeding risk, and the perioperative management of oral anticoagulation.

The key issue in the anemic patient is to determine the need for preoperative diagnostic evaluation and the need for transfusion. When feasible, the diagnostic evaluation of the patient with previously unrecognized anemia should be done prior to surgery because certain types of anemia (particularly sickle cell disease and immune hemolytic anemias) may have implications for perioperative management. Preoperative anemia is common, with a prevalence of 43% in a large cohort of elderly veterans undergoing surgery. In this cohort, morbidity and mortality increased as the preoperative hemoglobin level decreased, even after adjusting for comorbidities. This finding was confirmed in a study of patients undergoing CABG, where the presence of preoperative anemia independently predicted the composite outcome of postoperative death, stroke, or acute kidney failure. No data exist to identify a specific preoperative hemoglobin level that should prompt transfusion prior to surgery. It is also not known whether such transfusions will improve postoperative outcomes. Determination of the need for preoperative transfusion in an individual patient must consider factors other than the absolute hemoglobin level, including the presence of cardiopulmonary disease, the type of surgery, and the likely severity of surgical blood loss. The few studies that have compared different postoperative transfusion thresholds failed to demonstrate improved outcomes with a more aggressive transfusion strategy. The traditional recommendation had been to maintain a hemoglobin concentration greater than 10 g/dL. This may be too cautious in otherwise young and healthy patients. In fact, several observational studies and one randomized trial (which included 305 postoperative patients) have not found a benefit to transfusion above a threshold of 7 g/dL.

In a randomized trial of patients who underwent cardiac surgery, the use of enalapril postoperatively was associated with a significantly slower recovery in the hemoglobin level. The medical consultant should be aware that enalapril, and perhaps all angiotensin-converting enzyme inhibitors, may slow the recovery from postoperative anemia.

The most important component of the bleeding risk assessment is a directed bleeding history (see Table 3–1). Patients who are reliable historians and who reveal no suggestion of abnormal bleeding on directed bleeding history and physical examination are at very low risk for having an occult bleeding disorder. Laboratory tests of hemostatic parameters in these patients are generally not needed. When the directed bleeding history is unreliable or incomplete or when abnormal bleeding is suggested, a formal evaluation of hemostasis should be done prior to surgery and should include measurement of the prothrombin time, activated partial thromboplastin time, and platelet count (see Chapter 13: Blood Disorders).

Patients receiving long-term oral anticoagulation are at risk for thromboembolic complications when an operation requires interruption of their therapy. In a cohort study of 1293 interruptions of warfarin therapy for invasive procedures, the 30-day thromboembolic risk was 0.7%. There are insufficient data to determine the excess risk incurred by holding warfarin therapy or whether this risk may be mitigated through the practice of "bridging" anticoagulation, where unfractionated or low-molecular-weight heparin is administered parenterally while oral anticoagulants are held until just prior to surgery. The bleeding risk associated with bridging anticoagulation can be substantial. Patients in this cohort who received bridging anticoagulation had a 13% incidence of clinically significant bleeding, compared with 0.8% for patients who did not receive bridging anticoagulation. Although firm evidence-based guidelines for perioperative bridging are lacking, most experts recommend bridging therapy only in patients at high risk for thromboembolism. It is important to consider the patient's preferences when weighing the risks and consequences of a thromboembolic event versus major bleeding. A practical approach to perioperative anticoagulation management is shown in Table 3–5.

Table 3–5. Recommendations for perioperative anticoagulation management.

Thromboembolic Risk without Anticoagulation	**Recommendation**
Low (< 8% annual risk) (eg, atrial fibrillation or mechanical bileaflet aortic	1. Stop oral anticoagulation 4–5 days

valve prosthesis with fewer than two other stroke risk factors)	before surgery 2. Measure INR the day before surgery to confirm that it is < 1.6 3. Resume oral anticoagulation the night of surgery, if possible 4. No bridging
High (> 8% annual risk) (eg, atrial fibrillation or mechanical heart valve with prior stroke, mechanical mitral valve prosthesis, arterial thromboembolism < 1 month ago, or venous thrombosis < 3 months ago)	1. Stop oral anticoagulation 4–5 days before surgery 2. Measure INR the day before surgery to confirm that it is < 1.6 3. Begin therapeutic dose UH or LMWH 2–3 days after stopping oral anticoagulation, and discontinue it 12–24 hours before surgery 4. Resume oral anticoagulation the night of surgery, if possible

	5. If procedure has a low risk of bleeding, consider therapeutic dose UH or LMWH beginning 24 hours after surgery and continuing until the INR is therapeutic

LMWH, low-molecular-weight heparin; UH, unfractionated heparin.

Neurologic Evaluation

Delirium occurs after major surgery in 5–50% of patients over the age of 50 years and is particularly common after hip fracture repair and aortic surgery, occurring in 30–60% of such patients. Postoperative delirium has been associated with higher rates of major postoperative cardiac and pulmonary complications, poor functional recovery, an increased length of hospital stay, an increased risk of subsequent dementia and functional decline, and increased mortality at 1 and 5 years. Several preoperative and postoperative factors, most notably age, preoperative cognitive impairment, preoperative psychotropic drug use, postoperative use of meperidine, and postoperative hyperglycemia have been associated with the development of postoperative delirium. Patients with multiple risk factors are at especially high risk. Delirium occurred in half of the patients with at least three of the risk factors listed in Table 3–6.

Table 3–6. Risk factors for the development of postoperative delirium.
Preoperative factors

Age > 70 years
Alcohol abuse
Cognitive impairment
Poor physical function status
Markedly abnormal serum sodium, potassium, or glucose level
Aortic, thoracic, hip fracture surgery, or emergency surgery
Postoperative factors
Use of meperidine or benzodiazepines, anticholinergics, antihistamines
Postoperative hematocrit < 30%
Use of urinary catheters

Two types of delirium reducing interventions have been evaluated: focused geriatric care and psychotropic medications. In a randomized, controlled trial of hip fracture surgery patients, those who received daily visits and targeted recommendations from a geriatrician had a lower risk of postoperative delirium (32%) than the control patients (50%). The most frequent interventions to prevent delirium were maintenance of the hematocrit greater than 30%; minimizing the use of benzodiazepines and anticholinergic and antihistamine medications; maintenance of regular bowel function; and early discontinuation of urinary catheters. Other studies comparing postoperative care in specialized geriatrics units with standard orthopedics wards have shown similar reductions in the incidence of delirium. Limited data support the use of neuroleptic medications to prevent postoperative delirium. A randomized trial in cardiac surgery patients demonstrated that risperidone (1 mg sublingual after regaining consciousness) reduced the incidence of postoperative delirium compared with placebo (11.1% vs. 31.7%). Another trial found that prophylactic oral haloperidol in orthopedic surgery patients failed to prevent delirium but did reduce its severity and duration. Postoperative cognitive dysfunction is defined as a reduction in memory, language comprehension, visuospatial comprehension, attention, or concentration. Postoperative cognitive dysfunction may occur in up to 25% patients after cardiopulmonary bypass and in 15% of patients after major noncardiac surgery. The symptoms are generally transient, lasting less than 3 months. It is more common in older patients and occurs with equal frequency after general or regional anesthesia.

Stroke may occur in 1–6% of patients undergoing cardiac or carotid artery surgery, but it occurs in less than 1% of all other surgical procedures. Most of the available data on postoperative stroke are in cardiac surgery patients. Most postoperative strokes are embolic in origin, and about half occur within the first postoperative day. Stroke after cardiac surgery is associated with significantly increased mortality, up to 22% in some studies. The risk factors for stroke after cardiac surgery include age > 60 years, a calcified aorta, prior stroke, symptomatic carotid stenosis > 50%, peripheral vascular disease, cigarette smoking, diabetes mellitus, and renal failure. Most studies suggest that asymptomatic carotid bruits are associated with little or no increased risk of stroke in noncardiac, noncarotid surgery. The importance of asymptomatic carotid artery stenoses > 50% is not known. Postoperative heart failure, hypovolemia, and hyperglycemia may also increase the risk of stroke.

Prophylactic carotid endarterectomy in most patients with asymptomatic carotid artery disease is unlikely to be beneficial. On the other hand, patients with carotid disease who are candidates for carotid endarterectomy anyway (see Chapter 12: Blood Vessel & Lymphatic Disorders) should probably have the carotid surgery prior to the elective surgery. In a recent observational study of 1566 patients who underwent carotid endarterectomy, the use of a statin medication was associated with a significant reduction in the rate of perioperative stroke and overall mortality. Given the broad indications for statin therapy in patients with vascular disease, it is prudent to begin statin treatment in patients with appropriate indications prior to their undergoing carotid surgery.

Management of Endocrine Diseases

Diabetes Mellitus

Patients with diabetes are at increased risk for postoperative infections, particularly those involving the surgical site. Patients with a preoperative hemoglobin A_{1c} < 7% have roughly half the risk for developing a postoperative infection compared with those with a hemoglobin A_{1c} > 7%. Furthermore, diabetic patients are more likely to have cardiovascular disease and thus are at increased risk for postoperative cardiac complications. The most challenging issue in diabetics, however, is the maintenance of glucose control during the perioperative period. The increased secretion of cortisol, epinephrine, glucagon, and growth hormone during surgery is associated with insulin resistance and hyperglycemia in diabetic patients. The goal of management is the prevention of severe hyperglycemia or hypoglycemia in the perioperative period.

The ideal blood glucose level is not known, but studies suggest that tighter perioperative glycemic control leads to better clinical outcomes. Existing data pertain primarily to cardiac surgery patients. In observational studies, cardiac surgery patients with mean postoperative glucose levels < 180 mg/dL had fewer serious surgical site infections, a lower risk of acute kidney failure, and a shorter hospital stay than patients with higher mean levels. In a study of 1200 patients in a critical care unit, most of whom had undergone cardiac surgery, those randomized to strict normalization of serum glucose (80–

110 mg/dL) had significantly less morbidity and a shorter length of stay in the critical care unit than patients who were treated only for serum glucose > 215 mg/dL. Based on these data, current guidelines recommend maintaining perioperative glucose levels as close to 110 mg/dL as possible in critically ill patients and between 90-130 mg/dL before meals in other patients. These goals must be adjusted based on a patient's individual circumstances, including their risk of hypoglycemia.

The specific pharmacologic management of diabetes during the perioperative period depends on the type of diabetes (insulin-dependent or not), the level of glycemic control, and the type and length of surgery. In general, patients who require insulin to control the diabetes (whether type 1 or type 2) will need intraoperative insulin with any surgical procedure. Patients with type 2 diabetes who take oral agents may require insulin during major or prolonged surgery. Perioperative management of all diabetic patients requires frequent blood glucose monitoring to prevent hypoglycemia and to ensure prompt treatment of hyperglycemia. Recommendations for glycemic control in patients who generally do not need intraoperative insulin are shown in Table 3–7. For patients who do require intraoperative insulin, no single regimen has been found to be superior in comparative trials. Three commonly used insulin administration methods are shown in Table 3–8. The subcutaneous route is used most often because it is easier to access and is less expensive. Intravenous insulin, which offers more rapid onset, shorter duration of action, and ease of dose titration, may be preferable for patients who are in the intensive care unit, patients who have poorly controlled diabetes, and patients who are undergoing cardiac surgery. Perioperative use of corticosteroids, common in neurosurgical and organ transplant procedures, increases glucose intolerance. Patients receiving corticosteroids often require additional regular insulin with meals, while their fasting glucose levels may remain relatively unchanged.

Table 3–7. Perioperative management of diabetic patients who do not need insulin.

Patient	**Recommended Management**
Diabetes well controlled on diet alone	Measure glucose every 4 hours while fasting or NPO and give subcutaneous regular insulin as needed to maintain blood glucose < 130 mg/dL
	Avoid glucose-containing solutions during surgery
Diabetes well controlled on an oral sulfonylurea,	The last dose of medication should be taken on the evening

metformin, or a thiazolidinedione	before surgery
	Measure glucose every 4 hours while fasting or NPO and give subcutaneous regular insulin as needed to maintain blood glucose < 130 mg/dL
	Measure blood glucose level every 4 hours (or more frequently as indicated) during surgery
	Resume oral hypoglycemic therapy when the patient returns to baseline diet

NPO, nothing by mouth.

Table 3–8. Intraoperative insulin administration methods.

Method	**Intravenous Insulin Administration**	**Glucose Administration**	**Blood Glucose Monitoring**
Subcutaneous insulin	One-half to two-thirds of the usual dose of insulin is	Infuse 5% glucose-containing solution at a	Every 2–4 hours beginning the

	administered on the morning of surgery	rate of at least 100 mL/h beginning on the morning of surgery and continuing until the patient begins eating	morning of surgery
Continuous intravenous insulin infusion in glucose-containing solution	On the morning of surgery, infuse 5–10% glucose solution containing 5–15 units regular insulin per liter of solution at a rate of 100 mL/h. This provides 0.5–1.5 units of insulin per hour. Additional insulin may be added as needed to keep blood sugar 100–200 mg/dL.		Every 2–4 hours during intravenous insulin infusion
Separate intravenous insulin and glucose infusions	Infuse intravenous regular insulin at a rate of 0.5–1.5 units/h, adjusting as needed to keep	Infuse 5–10% glucose-containing solution at a rate of 100 mL/h	Every 2–4 hours during intravenous insulin infusion

	blood sugar 100–200 mg/dL		

Corticosteroid Replacement

Perioperative complications (predominantly hypotension) resulting from primary or secondary adrenocortical insufficiency are rare. The common practice of administering high-dose corticosteroids during the perioperative period in patients at risk for adrenocortical has not been rigorously studied. Limited data suggest that simply continuing long-term maintenance corticosteroid therapy, without additional "stress" doses of corticosteroids, is sufficient to prevent perioperative complications in patients with secondary adrenal suppression. While definitive recommendations regarding perioperative corticosteroid therapy cannot be made, a conservative approach would be to consider any patient to be at risk for having adrenocortical insufficiency who has received either the equivalent of 20 mg of prednisone daily for 3 weeks or the equivalent of 7.5 mg of prednisone daily for 1 month within the past year. A commonly used regimen is 50–100 mg of hydrocortisone given intravenously every 8 hours beginning before induction of anesthesia and continuing for 24-48 hours. Tapering the dose is not necessary. Patients being maintained on long-term corticosteroids should also continue their usual dose throughout the perioperative period.

Thyroid Disease

Severe symptomatic hypothyroidism has been associated with several perioperative complications, including intraoperative hypotension, CHF, cardiac arrest, and death. Elective surgery should be delayed in patients with severe hypothyroidism until adequate thyroid hormone replacement can be achieved. Similarly, patients with symptomatic hyperthyroidism are at risk for perioperative thyroid storm and should not undergo elective surgery until their thyrotoxicosis is controlled. An endocrinologist should be consulted if emergency surgery is needed in such patients. Conversely, patients with asymptomatic or mild hypothyroidism generally tolerate surgery well, with only a slight increase in the incidence of intraoperative hypotension; surgery need not be delayed for the month or more required to ensure adequate thyroid hormone replacement.

Hypocalcemia

Hypocalcemia occurs in 5–25% of patients after total thyroidectomy as a result of ischemia or injury to the parathyroid glands. In most cases, the hypocalcemia develops 24–48 hours after surgery and is temporary. Serum calcium should be measured frequently, beginning no more than 6 hours after surgery. In patients for whom the serum calcium level increases between 6 and 12 hours (positive slope) after surgery, the risk of developing clinically significant hypocalcemia is quite low. In addition, an immediate postoperative rapid parathyroid hormone (rPTH) level > 12 pg/mL predicts a very low risk of subsequent hypocalcemia. On the other hand, patients who have a negative calcium slope or a rPTH (< 12 pg/mL) have a substantial risk of developing symptomatic hypocalcemia. Such patients should be monitored closely for the development of symptoms of hypocalcemia and may be considered for prophylactic treatment with oral calcium and vitamin D.

Kidney Disease

The risk for development of a significant reduction in kidney function, including dialysis requiring acute kidney failure, after major surgery has been estimated to be between 0.5% and 10%. The mortality associated with the development of postoperative acute kidney failure that requires dialysis exceeds 50%. Risk factors that have been associated with postoperative deterioration in kidney function are shown in Table 3–9. The most important of these are the presence of preoperative kidney dysfunction and cardiac or vascular surgery. In patients with normal preoperative kidney function (calculated creatinine clearance > 80 mL/min) undergoing major noncardiac surgery, 0.8% developed significant acute kidney injury and 0.1% required renal replacement therapy. Several medications, including "renal dose" dopamine, mannitol, *N*-acetylcysteine, and furosemide, have been evaluated in an attempt to preserve kidney function during the perioperative period. None of these, however, have proved effective in clinical trials. Maintenance of adequate intravascular volume is likely to be the most effective method to reduce the risk of perioperative deterioration in kidney function.

Table 3–9. Risk factors for the development of postoperative acute renal failure.
Preoperative chronic renal insufficiency
Aortic surgery
Cardiac surgery
Peripheral vascular disease
Severe heart failure
Preoperative jaundice
Age > 70 years
Diabetes mellitus
COPD requiring daily bronchodilator therapy

COPD, chronic obstructive pulmonary disease.

Although the mortality rate for elective major surgery is low (1–4%) in patients with dialysis-dependent chronic kidney disease, the risk for perioperative complications, including postoperative hyperkalemia, pneumonia, fluid overload, and bleeding, is substantially increased. Postoperative hyperkalemia requiring emergent hemodialysis has been reported to occur in 20–30% of patients. Patients should undergo dialysis preoperatively within 24 hours before surgery, and their serum electrolyte levels should be measured just prior to surgery and monitored closely during the postoperative period.

Antibiotic Prophylaxis of Surgical Site Infections

Surgical site infection is a common and important cause of morbidity and prolonged hospital stays. There are an estimated 0.5–1 million surgical site infections annually in the United States. Surgical site infection is estimated to occur in roughly 4% of general or vascular operations. For most major procedures, the use of prophylactic antibiotics has been demonstrated to reduce the incidence of surgical site infections significantly. For example, antibiotic prophylaxis in colorectal surgery reduces the incidence of surgical site infection from 25–50% to below 20%. In addition, in a case control study of Medicare beneficiaries, the use of preoperative antibiotics within 2 hours of surgery was associated with a twofold reduction in 60-day mortality. Prophylactic antibiotics are considered standard care for all but "clean" surgical procedures. Clean procedures are those that are elective, nontraumatic, not associated with acute inflammation, and that do not enter the respiratory, gastrointestinal, biliary, or genitourinary tract. The surgical site infection rate for clean procedures is thought to be roughly 2%. However, in certain clean procedures, such as those that involve the insertion of a foreign body or breast cancer surgery, antibiotic prophylaxis is still recommended because the consequences of infection are serious. Antibiotic prophylaxis recommendations for a variety of procedures are shown in Table 3–10.

Table 3–10. Recommended antibiotic prophylaxis for selected surgical procedures.

Procedure	**Recommended Antibiotic**	**Adult Dose**
Superficial cutaneous	None	
Head and neck	Cefazolin	1–2 g intravenously
Neurologic	Cefazolin	1–2 g intravenously
Thoracic	Cefazolin	1–2 g intravenously
Noncardiac vascular	Cefazolin	1–2 g intravenously
Orthopedic, clean, without implantation of foreign material	None	
Orthopedic, all other	Cefazolin	1–2 g intravenously
Cesarean delivery	Cefazolin	2 g intravenously
Hysterectomy	Cefazolin or	1–2 g

	cefotetan	intravenously
Breast cancer surgery	Cefazolin	1–2 g intravenously
Gastroduodenal	Cefazolin (high risk only)[1]	1–2 g intravenously
Biliary	Cefazolin (high risk only)[1]	1–2 g intravenously
Urologic	Cefazolin (high risk only)[2]	1–2 g intravenously
Appendectomy for uncomplicated appendicitis	Cefotetan or cefoxitin	1–2 g intravenously
Colorectal[3]	Ertapenem or	1 g intravenously
	cefotetan or cefoxitin	1–2 g intravenously every 8 hours for 3 total doses
	–or–	
	Neomycin sulfate plus erythromycin base	1 g of each agent given orally at 19, 18, and 9 hours before surgery

	Cefazolin (high risk only)[1]	1–2 g intravenously
Breast and hernia	Cefazolin (high risk only)[1]	1–2 g intravenously

[1] High risk defined as patients with risk factors for surgical site infection such as older age, diabetes, or multiple medical comorbidities.

[2] High risk defined as prolonged postoperative catheterization or positive urine cultures.

[3] All patients should have mechanical bowel preparation with polyethylene glycol, mannitol, or magnesium citrate.

Multiple studies have evaluated the effectiveness of different antibiotic regimens for various surgical procedures. In most cases, no single antibiotic regimen has been shown to be superior. Several general conclusions can be drawn from these data. First, substantial evidence suggests that a single dose of an appropriate intravenous antibiotic—or combination of antibiotics—is as effective as multiple-dose regimens that extend into the postoperative period. For longer procedures, the dose should be repeated every 3–4 hours to ensure maintenance of a therapeutic serum level. In colorectal surgery, however, three doses of an intravenous cephalosporin have been shown to reduce surgical site infection incidence compared with a single dose. Similarly, at least 24 hours of postoperative antibiotic therapy is recommended after cardiac surgery. Second, for most procedures, a first-generation cephalosporin is as effective as later-generation agents. However, in a large randomized trial of colorectal surgery patients, the use of prophylactic ertapenem significantly reduced the surgical site infection rate compared to that for cefotetan. Third, prophylactic antibiotics should be given intravenously at induction of anesthesia or roughly 30–60 minutes prior to the skin incision. Although the type of procedure is the main factor determining the risk of developing a surgical site infection, certain patient factors have been associated with increased risk, including diabetes, older age, obesity, heavy alcohol consumption, admission from a long-term care facility, and multiple medical comorbidities.

Other strategies to prevent surgical site infections have proven to be controversial. Evidence suggests that nasal carriage with *Staphylococcus aureus* is associated with a twofold to ninefold increased risk of surgical site and catheter-related infections in surgical patients. Treatment of nasal carriers of *S aureus* with 2% mupirocin ointment (twice daily intranasally for 3 days) prior to cardiac surgery decreases the risk of surgical site infections. However, in a recent large prospective cohort study, universal screening for methicillin-resistant *S aureus* in surgical patients failed to reduce infection rates from this pathogen. Data on the use of supplemental oxygen to prevent surgical site infections are also mixed. An early trial found that high concentration oxygen delivered in the immediate postoperative period reduced surgical site infections. The most recent study found an increased risk of surgical site infections with the use of 80% oxygen compared with 35% postoperatively. Thus, high-flow supplemental oxygen specifically to prevent these infections is presently not recommended. Preoperative bathing with antiseptic agents and preoperative hair removal are common practices but have not demonstrated a reduction in surgical site infections in randomized trials. The use of razors for hair removal actually seems to increase the risk of surgical site infections and is therefore specifically not recommended. If preoperative hair removal is indicated, the use of clippers is preferred.

Geriatric Disorders: Introduction

The impressive successes of medicine and public health over the past century have made it possible for elderly persons to live longer and healthier than ever before. Persons over the age of 65 will account for 20% of the population and more than 50% of all health care by 2030. Thus, most physicians will spend a significant portion of their professional lives dealing with older adults' health care.

Older persons are remarkably heterogeneous: they vary in health status, prognosis, and preferences for care. Many persons in their 60s are healthy and can expect to live another 30 years or longer. Yet, chronic diseases that will cause disability and ultimately death will develop in nearly all older persons. Therefore, physicians caring for older adults must have skills in managing multiple comorbidities and wisely guiding the patient in both "curative" and "palliative care."

General Principles of Geriatric Care

The following principles are helpful to keep in mind while caring for older adults:

1. Many disorders are multifactorial in origin and are best managed by multifactorial interventions.
2. Diseases often present atypically.
3. Not all abnormalities require evaluation and

treatment.
4. Complex medication regimens, adherence problems, and polypharmacy are common challenges.

Comorbidities are common in older people, and the diagnostic "law of parsimony" often does not apply. For example, fever, anemia, and a heart murmur are almost always diagnostic of endocarditis in a younger patient; however, in an older patient, three different explanations—a viral illness, colon cancer, and aortic sclerosis—might be as likely as the unifying diagnosis of endocarditis.

Disease presentation is often atypical in elderly patients. A disorder in one organ system may lead to symptoms in another, especially one that is compromised by preexisting disease. A limited number of presenting symptoms—ie, confusion, falling, incontinence, dizziness, and functional decline—predominate irrespective of the underlying disease. Thus, regardless of the presenting symptom in older people, the differential diagnosis is often similar. An 80-year-old person with new falls and confusion could have pneumonia, an acute myocardial infarction, a stroke, or a urinary tract infection.

Because many geriatric syndromes have multiple causes, multiple targeted interventions may be a more realistic approach than trying to find a "cure." For example, dizziness is often multifactorial in older adults. A clinician who focuses on finding a single diagnosis may become frustrated, while a clinician who works on multiple problems, such as correcting vision, prescribing physical therapy focused on strength and balance, and reducing sedating medications, might meet with more success.

Many abnormal findings in younger patients are relatively common in older people and may not be responsible for a particular symptom. Such findings may include asymptomatic bacteriuria, premature ventricular contractions, and slowed reaction time. In addition, many older patients with multiple comorbidities may have laboratory abnormalities that, while pathologic, may not be clinically important. A complete work-up for a mild anemia of chronic disease in a person with multiple other issues might be burdensome to the patient with little chance of impacting quality of life or longevity. While abnormalities should be acknowledged in the medical record, they can be addressed in order of priority, with the patient's goals (symptom management, desire for longevity) dictating the evaluation strategy.

Many older patients have to manage complex medication regimens, particularly those who have multiple comorbidities. Drug side effects can occur with low doses of drugs that usually produce no side effects in younger people. For instance, a mild anticholinergic agent (eg, diphenhydramine) may cause confusion, loop diuretics may precipitate urinary incontinence, digoxin may induce anorexia even with normal serum levels, and nonprescription sympathomimetics may result in urinary retention in older men with mild prostatic obstruction.

Assessment of the Older Adult

Comprehensive assessment addresses three topics in addition to conventional assessment of symptoms and diseases: prognosis, values and preferences, and ability to function independently. Comprehensive assessment is warranted before major clinical decisions (eg, whether major surgery should be performed, or whether a patient should be treated for pneumonia at home or in the hospital), and each topic merits at least brief consideration in each clinical decision.

Assessment of Prognosis

When an older person's life expectancy is greater than 10 years (ie, 50% of similar persons live longer than 10 years), it is reasonable to consider effective tests and treatments much as they are considered in younger persons. When life expectancy is less than 10 years (and especially when it is much less), choices of tests and treatments should be made on the basis of their ability to improve that particular patient's prognosis and quality of life in the shorter term of that patient's life expectancy.

The relative benefits and harms of tests and treatments often change as prognosis worsens.

When an older patient's clinical situation is dominated by a single disease process (eg, lung cancer metastatic to brain or acute myocardial infarction with left ventricular failure), prognosis can be estimated well with a disease-specific instrument. Even in this situation, however, prognosis generally worsens with age (especially age greater than 90 years) and with the presence of serious age-related conditions, such as dementia, malnutrition, or impaired ability to walk.

When an older patient's clinical situation is not dominated by a single disease process, prognosis can be estimated initially by considering the patient's age, gender, and general health (Figure 4–1: illustration). For example, less than 25% of men age 95 years will live 5 years, whereas nearly 75% of women age 70 years will live 10 years.

Figure 4–1.

Median life expectancy of older women and men. (Adapted, with permission, from Walter LC et al. Screening for colorectal, breast, and cervical cancer in the elderly: a review of the evidence. Am J Med. 2005

Oct;118(10):1078–86.)

The prognosis of older persons living at home can be estimated by considering age, gender, comorbid conditions, and function (Table 4–1). The prognosis of older persons discharged from the hospital is worse than that of those living at home and can be estimated by considering gender, comorbid conditions, and function at discharge (Table 4–2). The sum of risk points indicates the mortality rate for similar patients.

Table 4–1. Prognostic factors, "risk points," and 4-year mortality rates for older persons living at home.

Prognostic Factor	**Risk Points**
Age	
60–64 years	1
64–69 years	2

Assessment of Values & Preferences

Values and preferences are determined by speaking directly with a patient or, when the patient cannot express preferences reliably, with the patient's surrogate. Values and preferences can be assessed most readily in the context of a specific medical decision. For example, the clinician might ask a patient considering a hip replacement, "How would you like your hip pain and function to be different? Tell me about the risk and discomfort you are willing to go through to achieve that improvement."

In assessing values and preferences, it is important to keep in mind the following:

1. Patients are experts about their preferences for outcomes and experiences; however, they often do

not have adequate information to express informed preferences for specific tests or treatments.

2. Patients' preferences often change over time. For example, some patients find living with a certain degree of disability more acceptable than they thought before experiencing the disability.

Assessment of Function

People often lose function in multiple domains as they age, with the results that they may not be able to do some activities as quickly or capably and may need assistance with other activities. Assessment of function improves prognostic estimates (see above). Assessment of function is essential to determining an individual's needs in the context of their values and preferences, and the possible effects of prescribed treatment.

About one-fourth of patients over 65 have impairments in their IADLs (instrumental activities of daily living: transportation, shopping, cooking, using the telephone, managing money, taking medications, housecleaning, laundry) or ADLs (basic activities of daily living: bathing, dressing, eating, transferring from bed to chair, continence, toileting). Half of those persons older than 85 years have these latter impairments.

In general, persons who need help only with IADLs can usually live independently with minimal supports, such as financial services (eg, a representative payee) or a chore worker. If institutional care is needed, residential care, board-and-care, or assisted living is usually sufficient. While many persons who need help with ADLs may require a nursing home level of care, most live at home with caregivers and other community services (eg, day care).

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Caregiver Issues

Most elders with functional impairment live in the community with the help of an "informal" caregiver, most commonly a spouse or daughter. The health and well-being of the patient and caregiver are closely linked. High levels of functional dependency place an enormous burden on a caregiver, and may result in caregiver "burnout," depression, morbidity, and even increased mortality.

An older patient’s need for nursing home placement is often better predicted from assessment of the caregiver characteristics and stress than the severity of the patient’s illness. Therefore, part of caring for a frail elder involves paying attention to the well-being of the caregiver. The older patient who is also a caregiver is at risk for depression and should be screened for it. For the stressed caregiver, a social worker may help identify programs such as caregiver support groups, respite programs, adult day care, or hired home health aides.

Functional Screening Instrument

Functional screening should include assessment of ADL and IADL and questions to detect weight loss, falls, incontinence, depressed mood, self neglect, fear for personal safety, and common serious impairments (eg, hearing, vision, cognition, and mobility) (eFigure 4–1.1). Standard functional screening measures may not be useful in capturing subtle impairments in highly functional independent elders. One technique for these patients is to identify and regularly ask about a target activity, such as bowling or gardening. If the patient begins to have trouble with or discontinues such an "advanced activity of daily living," it may indicate early impairment, such as dementia, incontinence, or worsening hearing loss, which additional gentle questioning or assessment may uncover.

eFigure 4–1.1.

Simple geriatric screen. PT, physical therapy; DIAPPERS, delirium, infection, atrophic urethritis or vaginitis, pharmaceuticals, psychological factors, excess urinary output, restricted mobility, stool impaction; PVR, postvoid residual; GDS, Geriatric Depression Screen; APS, Adult Protective Services; OT, occupational therapy; BMI, body mass index; MMSE, Mini-Mental State Exam. (Adapted, with permission, from Lachs M et al. A simple procedure for general screening for functional disability in elderly patients. Ann Intern Med. 1990 May 1;112(9):699–706 and Moore AA et al. Screening for common problems in ambulatory elderly: clinical confirmation of a screening instrument. Am J Med. 1996 Apr;100(4):438–43.)

Busy primary care providers may find it more manageable to perform the elements of functional geriatric assessment over three or four visits or to train office personnel to perform some elements of the assessment.

Dementia

Essentials of Diagnosis

- Progressive decline of intellectual function.
- Loss of short-term memory and at least one other cognitive deficit.
- Deficit severe enough to cause impairment of function.
- Not delirious.

General Considerations

Dementia is an acquired persistent and progressive impairment in intellectual function, with compromise of memory and at least one other cognitive domain, most commonly language impairment, apraxia (inability to perform motor tasks, such as cutting a loaf of bread, despite intact motor function), agnosia (inability to recognize objects), and impaired executive function (poor abstraction, mental flexibility, planning, and judgment). The diagnosis of dementia requires a significant decline in function that is severe enough to interfere with work or social life.

Dementia has a prevalence that doubles every 5 years in the older population, reaching 30–50% at age 85. Women suffer disproportionately, both as patients (even after age adjustment) and as caregivers. Alzheimer disease (AD) accounts for roughly two-thirds of dementia cases in the United States, with vascular dementia (either alone or combined with AD) and dementia with Lewy bodies accounting for much of the rest. Some of the risk factors for AD are older age, family history, lower education level, and female gender. Education, cognitive "exercises," and social support may be protective. Risk factors for vascular dementia are those for stroke, ie, older age, hypertension, cigarette use, atrial fibrillation, diabetes mellitus, and hyperlipidemia.

Depression and delirium are also common in elders, may coexist with dementia, and may also present with cognitive impairment. Depression is a common concomitant of early dementia. A patient with depression and cognitive impairment whose intellectual function improves with treatment of the mood disorder has an almost fivefold greater risk of suffering irreversible dementia later in life. Delirium, characterized by acute confusion, occurs much more commonly in patients with underlying dementia.

Clinical Findings

Screening

Cognitive impairment

Although there is no consensus at present on whether older patients should be screened for dementia, the benefits of early detection include identification of potentially reversible causes, planning for the future (including discussing values and completing advance care directives), and providing support and counseling for the caregiver.

The combination of a clock drawing task with a three-item word recall (also known as the "mini-cog") is a simple screening test that is fairly quick to administer. Although a number of different methods for administering and scoring the clock draw test have been described, the authors of this chapter favor the approach of pre-drawing a four inch circle on a sheet of paper and instructing the patient to "draw a clock" with the time set at 10 minutes after 11. Scores are classified as normal, almost normal, or abnormal. When a patient is able to draw a clock normally and can remember all 3 objects, dementia is unlikely. When a patient fails this simple screen, further cognitive evaluation with the Folstein Mini Mental State Exam (MMSE) or other instruments is warranted.

Decision-making capacity

It is common for a cognitively impaired elder to face a serious medical decision and for the clinicians involved in his care to ascertain whether the capacity exists to make the choice. There are five components of a thorough assessment: (1) ability to express a choice; (2) understanding relevant information about the risks and benefits of planned therapy and the alternatives, in the context of one's values, including no treatment; (3)

comprehension of the problem and its consequences; (4) ability to reason; and (5) consistency. A patient's choice should follow rationally from an understanding of the consequences.

Cultural sensitivity must be used in applying these five components to people of various cultural backgrounds. Decision-making capacity varies over time: A delirious patient may regain his capacity after an infection is treated, and so reassessments are often appropriate. Furthermore, the capacity to make a decision is a function of the decision in question. A woman with mild dementia may lack the capacity to consent to coronary artery bypass grafting yet retain the capacity to designate a surrogate decision maker.

Symptoms and Signs

The clinician can gather important information about the type of dementia that may be present by asking about: (1) the rate of progression of the deficits as well as their nature (including any personality or behavioral change); (2) the presence of other neurologic symptoms, particularly motor problems; (3) risk factors for HIV; (4) family history of dementia; and (5) medications, with particular attention to recent changes.

Work-up is directed at identifying any potentially reversible causes of dementia. However, such cases are indeed rare.

AD typically presents with early problems in memory and visuospatial abilities (eg, becoming lost in familiar surroundings, inability to copy a geometric design on paper), yet social graces may be retained despite advanced cognitive decline. Personality changes and behavioral difficulties (wandering, inappropriate sexual behavior, agitation) may develop as the disease progresses. Hallucinations may occur in moderate to severe dementia. End-stage disease is characterized by near-mutism; inability to sit up, hold up the head, or track objects with the eyes; difficulty with eating and swallowing; weight loss; bowel or bladder incontinence; and recurrent respiratory or urinary infections.

"Subcortical" dementias (eg, the dementia of Parkinson disease, and some cases of vascular dementia) are characterized by psychomotor slowing, reduced attention, early loss of executive function, and personality changes.

Dementia with Lewy bodies may be confused with delirium, as fluctuating cognitive impairment is frequently observed. Rigidity and bradykinesia are the primary signs, and tremor is rare. Response to dopaminergic agonist therapy is poor. Complex visual hallucinations—typically of people or animals—may be an early feature that can help distinguish dementia with Lewy bodies from AD. These patients demonstrate a hypersensitivity to neuroleptic therapy, and attempts to treat the hallucinations may lead to marked worsening of extrapyramidal symptoms.

Frontotemporal dementias are a group of diseases that include Pick disease, dementia associated with amyotrophic lateral sclerosis, and others. Patients manifest personality change (euphoria, disinhibition, apathy) and compulsive behaviors (often peculiar eating habits or hyperorality). In contrast to AD, visuospatial function is relatively preserved.

Dementia in association with motor findings, such as extrapyramidal features or ataxia, may represent a less common disorder (eg, progressive supranuclear palsy, corticobasal ganglionic degeneration, olivopontocerebellar atrophy).

Physical Examination

The neurologic examination emphasizes assessment of mental status but should also include evaluation for sensory deficits, possible previous strokes, parkinsonism, or peripheral neuropathy. The remainder of the physical examination should focus on identifying comorbid conditions that may aggravate the individual's disability.

Laboratory Findings

Laboratory studies should include a complete blood count, electrolytes, calcium, creatinine, glucose, thyroid-stimulating hormone (TSH), and vitamin B12 levels. HIV testing, RPR (rapid plasma reagin) test, heavy metal screen, and liver biochemical tests may be informative in selected patients but should not be considered part of routine testing.

Imaging

Most patients should receive neuroimaging as part of the diagnostic work-up to rule out subdural hematoma, tumor, previous stroke, and hydrocephalus (usually normal pressure). Those who are younger and those who have focal neurologic symptoms or signs, seizures, gait abnormalities, and an acute or subacute onset are most likely to yield positive findings and most likely to benefit from MRI scanning. In older patients with a more classic picture of AD in whom neuroimaging is desired, a noncontrast CT scan is sufficient.

Differential Diagnosis

Older individuals experience occasional difficulty retrieving items from memory (usually manifested as word-finding complaints) and experience a slowing in their rate of information processing. **Mild cognitive impairment** is an increasingly recognized condition in which a patient complains of memory problems, demonstrates mild deficits (most commonly in short-term memory) on formal testing, but does not meet criteria for dementia. Dementia will develop in more than half of people with mild cognitive impairment within 5 years. Acetylcholinesterase inhibitors have not consistently demonstrated a delay in the progression of mild cognitive impairment to AD. An elderly patient with intact cognition but with severe impairments in vision or hearing commonly becomes confused in an unfamiliar medical setting and consequently may be falsely labeled as demented. Cognitive testing is best performed after optimal correction of the sensory deficits.

Delirium can be distinguished from dementia by its acute onset, fluctuating course, and deficits in attention rather than memory. Because delirium and dementia often coexist, it may not be possible to determine how much impairment is attributable to each condition until the patient is fully recovered and back in their usual setting. Many medications have been associated with delirium and other types of cognitive impairment in older patients. Anticholinergic agents, hypnotics, neuroleptics, opioids, nonsteroidal anti-inflammatory drugs (NSAIDs), antihistamines (including H_2-antagonists), and corticosteroids are just some of the medications that have been associated with cognitive impairment in elders.

Treatment

Soon after diagnosis, patients and families should be made aware of the Alzheimer's Association (http://www.alz.org) as well as the wealth of helpful community and online resources and publications available. Caregiver support, education, and counseling can prevent or delay nursing home placement. Education should include the manifestations and natural history of dementia as well as the availability of local support services such as respite care. Even under the best of circumstances, caregiver stress can be substantial. Collaborative care models and disease management programs appear to improve the quality of care for patients with dementia.

Cognitive Impairment

Because demented patients have greatly diminished cognitive reserve, they are at high risk for experiencing acute cognitive or functional decline in the setting of new medical illness. Consequently, fragile cognitive status may be best maintained by ensuring that comorbid diseases such as congestive heart failure and infections are detected and treated.

Acetylcholinesterase inhibitors

The majority of experts recommend considering a trial of acetylcholinesterase inhibitors (eg, donepezil, galantamine, rivastigmine) in most patients with mild to moderate AD. These medications produce a modest improvement in cognitive function that is not likely to be detected in routine clinical encounters. Acetylcholinesterase inhibitors may also have similarly modest cognitive benefits in patients with vascular dementia or dementia with Lewy bodies. However, acetylcholinesterase inhibitors have not been shown to delay institutionalization or functional decline.

Starting doses, respectively, of donepezil, galantamine, and rivastigmine, are 5 mg orally once daily (maximum 10 mg once daily), 4 mg orally twice daily (maximum 12 mg twice daily), and 1.5 mg orally twice daily (maximum 6 mg twice daily). The doses are increased gradually as tolerated. The most bothersome side effects include diarrhea, nausea, anorexia, and weight loss. In those patients who have had no apparent benefit, experience side effects, or for whom the financial outlay is a burden, the authors of this chapter recommend a trial of discontinuation.

Memantine

In clinical trials, patients with more advanced disease have been shown to have statistical benefit from the use of memantine, an *N*- methyl-D-aspartate (NMDA) antagonist, with or without concomitant use of an acetylcholinesterase inhibitor. Long-term and meaningful functional outcomes have yet to be demonstrated.

Behavioral Problems

Nonpharmacologic approaches

Behavioral problems in demented patients are often best managed with a nonpharmacologic approach. Initially, it should be established that the problem is not unrecognized delirium, pain, urinary obstruction, or fecal impaction. It also helps to inquire whether the caregiver or institutional staff can tolerate the behavior, as it is often easier to find ways to accommodate to the behavior than to modify it. If not, the caregiver is asked to keep a brief log in which the behavior is described along with antecedent events and consequences. Recurring precipitants of the behavior are often found to be present or it may be that the behavior is rewarded—for example, by increased attention. Caregivers are taught to use simple language when communicating with the patient, to break down activities into simple component tasks, and to use a "distract, not confront" approach when the patient seems disturbed by a troublesome issue. Additional steps to address behavioral problems include the discontinuation of all medications except those considered absolutely necessary and correction, if possible, of sensory deficits.

Pharmacologic approaches

There is no clear consensus about pharmacologic approaches to treatment of behavioral problems in patients who have not benefited from nonpharmacologic therapies. The target symptoms—depression, anxiety, psychosis, mood lability, or pain—may suggest which class of medications might be most helpful in a given patient. Patients with depressive symptoms may show improvement with antidepressant therapy. Patients with dementia with Lewy bodies have shown clinically significant improvement in behavioral symptoms when treated with rivastigmine (3–6 mg orally twice daily).

For those with AD and agitation, no agents, including acetylcholinesterase inhibitors and antipsychotics, have demonstrated consistent efficacy. Despite the lack of strong evidence, antipsychotic medications have remained a mainstay for the treatment of behavioral disturbances, largely because of the lack of alternative agents. The newer atypical antipsychotic agents (risperidone, olanzapine, quetiapine, aripiprazole, clozapine, ziprasidone) are reported to be better tolerated than older agents but should be avoided in patients with vascular risk factors due to an increased risk of stroke and weight gain; they are also considerably more expensive. The US Food and Drug Administration has issued a public health advisory warning that atypical agents, when used to treat elderly demented patients with behavioral disturbances, increase mortality rates when compared with placebo. Studies have also linked haloperidol and other typical antipsychotics with increased mortality rates when used in patients with dementia. When the choice is made to use these agents, patients and caregivers should be carefully warned of the risks. Starting and target dosages should be much lower than those used in schizophrenia (eg, haloperidol, 0.5–2 mg orally; risperidone, 0.25–2 mg orally). Federal regulations require that if antipsychotic agents are used in treatment of a nursing home patient, drug reduction efforts must be made at least every 6 months.

Prognosis

Life expectancy after a diagnosis of AD is typically 3–15 years; it may be shorter than previously reported. Other neurodegenerative dementias, such as dementia with Lewy bodies, show more rapid decline. Hospice is often appropriate for patients with end-stage dementia.

When to Refer

Referral for neuropsychological testing may be helpful in the following circumstances: to distinguish dementia from depression, to diagnose dementia in persons of very poor education or very high premorbid intellect, and to aid diagnosis when impairment is mild.

Depression

Essentials of Diagnosis

- Depressed elders may not admit to depressed mood.
- Depression screening in elders should include a question about anhedonia.

General Considerations

Although the prevalence of major depression is similar in younger and older populations, depressive symptoms—often related to loss, disease, and life changes—may be present in more than 25% of elders. Depression is particularly common in hospitalized and institutionalized elders. Older single men have the highest suicide rate of any demographic group. Geriatric patients with depression are more likely to have somatic complaints, less likely to report depressed mood, and more likely to experience delusions than younger patients. In addition, depression may be an early symptom of a neurodegenerative condition such as dementia.

Clinical Findings

A simple two-question screen—which consists of asking "During the past 2 weeks, have you felt down, depressed, or hopeless?" and "During the past 2 weeks, have you felt little interest or pleasure in doing things?"—is highly sensitive for detecting major depression in persons over age 65. Positive responses can be followed up with more comprehensive, structured interviews, such as the

Geriatric Depression Scale (http://www.stanford.edu/~yesavage/) or the PHQ-9 (http://www.depression-primarycare.org).

Elderly patients with depressive symptoms should be questioned about medication use, since many drugs (eg, benzodiazepines, corticosteroids) may contribute to the clinical picture. Similarly, several medical problems can cause fatigue, lethargy, or hypoactive delirium, all of which may be mistaken for depression. Laboratory examination should include a complete blood count; liver, thyroid, and kidney function tests; and serum calcium. If delirium is in the differential diagnosis, the work-up should include a urinalysis and an electrocardiogram.

Treatment

Choice of antidepressant agent in elders is usually based on side effect profile and cost. In general, fluoxetine is avoided because of its long duration of action and tricyclic antidepressants are avoided because of their high anticholinergic side effects. Regardless of the drug chosen, many experts recommend starting elders at a relatively low dose, titrating to full dose slowly, and continuing for a longer trial (at least 9 weeks) before trying a different medication. Cognitive behavioral therapy can improve outcomes alone or in combination with medication therapy. Depressed elders may do better with a collaborative care model that includes socialization and other support elements than with usual care. Recurrence of major depression is common in elders; any elder with a history of depression should be closely monitored for recurrence and considered for longer-term maintenance medication therapy.

When to Refer

Referral should be considered for patients who have not responded to an initial antidepressant drug trial and for patients with have symptoms of mania, suicidality, or psychosis.

When to Admit

Patients who are suicidal, homicidal, psychotic, or a danger to self or others should be considered for acute psychiatric hospitalization.

Reynolds CF 3rd et al. Maintenance treatment of major depression in old age. N Engl J Med. 2006 Mar 16;354(11):1130–8. [PMID: 16540613]

Delirium

Essentials of Diagnosis

- Rapid onset and fluctuating course.
- Primary deficit in attention rather than memory.
- May be hypoactive or hyperactive.
- Dementia frequently coexists.

General Considerations

Delirium is an acute, fluctuating disturbance of consciousness, associated with a change in cognition or the development of perceptual disturbances (see also Chapter 25: Psychiatric Disorders). It is the pathophysiologic consequence of an underlying general medical condition such as infection, coronary ischemia, hypoxemia, or metabolic derangement. Delirium persists in up to 25% of patients and is associated with worse clinical outcomes (higher in-hospital and postdischarge mortality, longer lengths of stay, greater probability of placement in a nursing facility).

Although the acutely agitated elderly patient often comes to mind when considering delirium, many episodes are more subtle. Such quiet, or hypoactive, delirium may only be suspected if one notices new cognitive slowing or inattention.

Cognitive impairment is an important risk factor for delirium. Approximately 25% of delirious patients are demented, and 40% of demented hospitalized patients are delirious. Other risk factors are male sex, severe illness, hip fracture, fever or hypothermia, hypotension, malnutrition, polypharmacy and use of psychoactive medications, sensory impairment, use of restraints, use of intravenous lines or urinary catheters, metabolic disorders, depression, and alcoholism.

Clinical Findings

A key component of a delirium workup is review of medications because a large number of drugs, the addition of a new drug, or the discontinuation of a medication known to cause withdrawal symptoms are all associated with the development of delirium.

Laboratory evaluation of most patients should include a complete blood count, electrolytes, blood urea nitrogen (BUN) and serum creatinine, glucose, calcium, albumin, liver function studies, urinalysis, and electrocardiography. In selected cases, serum magnesium, serum drug levels, arterial blood gas measurements, blood cultures, chest radiography, urinary toxin screen, head CT scan, and lumbar puncture may be helpful.

Prevention

Prevention is the best approach in the management of delirium. Measures include improving cognition (frequent reorientation, activities, socialization with family and friends, when possible), sleep (massage, noise reduction, minimizing interruptions at night), mobility, vision (visual aids and adaptive equipment), hearing (portable amplifiers, cerumen disimpaction), and hydration status (volume repletion).

Treatment

Management of established episodes of delirium is largely supportive and includes treatment of any underlying causes, eliminating unnecessary medications, and avoidance of indwelling catheters and restraints. Antipsychotic agents (such as haloperidol, 0.5–1 mg, or quetiapine, 25 mg, at bedtime or twice daily) are considered the medication of choice when drug treatment of delirium is necessary. In emergency situations, starting haloperidol at 0.5 mg orally or intramuscularly and repeating every 30 minutes until the agitation is controlled may be necessary, but such treatment is often followed by prolonged sedation or other complications. Other medications (eg, trazodone, donepezil, mood stabilizers) have also been used, but evidence in support of these approaches is weak.

Most episodes of delirium clear in a matter of days after correction of the precipitant, but some patients suffer episodes of longer duration, and a few never return to their former baseline level of functioning. These individuals merit closer follow-up for the development of dementia if not already diagnosed.

When to Refer

If an initial evaluation does not reveal the cause of delirium or if entities other than delirium are in the differential diagnosis, referral to a neuropsychologist, neurologist, or geropsychiatrist should be considered.

When to Admit

Patients with delirium of unknown cause should be admitted for an expedited work-up if consistent with the patient's goals of care.

Young J et al. Delirium in older people. BMJ. 2007 Apr 21;334(7598):842–6. [PMID: 17446616]

Immobility

Although common in older people, reduced mobility is never normal and is often treatable if its causes are identified. Bedrest is an important cause of hospital-induced functional decline. Among hospitalized medical patients over 70, about 10% experience a decline in function, much of which results from preventable reductions in mobility.

The hazards of bed rest in older adults are multiple, serious, quick to develop, and slow to reverse. Deconditioning of the cardiovascular system occurs within days and involves fluid shifts, decreased cardiac output, decreased peak oxygen uptake, and increased resting heart rate. More striking changes occur in skeletal muscle, with loss of contractile velocity and strength. Pressure sores, deep venous thrombosis, and pulmonary embolism are additional serious risks. Within days after being confined to bed, the risk of postural hypotension, falls, and skin breakdown rises rapidly in the older patient. Moreover, recovery from these changes usually takes weeks to months.

Prevention & Treatment

When immobilization cannot be avoided, several measures can be used to minimize its consequences. Skin, particularly areas over pressure points, should be inspected at least daily. If the patient is unable to shift position, staff should do so every 2 hours. To minimize cardiovascular deconditioning, patients should be positioned as close to the upright position as possible, several times daily. To reduce the risks of contracture and weakness, range of motion and strengthening exercises should be started immediately and continued as long as the patient is in bed. Whenever possible, patients should assist with their own positioning, transferring, and self-care. As long as the patient remains immobilized, antithrombotic measures should be used if that is consistent with the patient's goals of care.

Avoiding restraints and discontinuing invasive devices (intravenous lines, urinary catheters) may increase an elderly patient's prospects for early mobility. Graduated ambulation should begin as soon as it is feasible. Advice from a physical therapist is often helpful both before and after discharge. Prior to discharge, physical therapists can recommend appropriate exercises and assistive devices; after discharge, they can recommend safety modifications and maintenance exercises.

Falls & Gait Disorders

Falls are the leading cause of nonfatal injuries in older persons, and their complications are the leading cause of death from injury in persons over age 65. Hip fractures are common precursors to functional impairment, nursing home placement, and death. Furthermore, fear of falling may lead some elders to restrict their activities. About one-third of people over 65 fall each year, and the frequency increases markedly with advancing age.

Every older person should be asked about falls; many will not volunteer such information. A thorough gait assessment should be performed in all older people. Gait and balance can be readily assessed by the "Up and Go Test," in which the patient is asked to stand up from a sitting position without use of hands, walk 10 feet, turn around, walk back, and sit down. Patients who take less than 10 seconds are usually normal, patients who take longer than 30 seconds tend to need assistance with many mobility tasks, and those in between tend to vary widely with respect to gait, balance, and function. The ability to recognize common patterns of gait disorders is an extremely useful clinical skill to develop. Examples of gait abnormalities and their causes are listed in Table 4–3.

Table 4–3. Evaluation of gait abnormalities.

Gait Abnormality	**Possible Cause**
Inability to stand without use of hands	Deconditioning Myopathy (hyperthyroidism, alcohol, statin-induced) Hip or knee pain
Unsteadiness upon standing	Orthostatic hypotension Balance problem (peripheral neuropathy, vision problem, vestibular, other central nervous system causes) Generalized weakness
Stagger with eyes closed	Often indicates that vision is compensating for another deficit
Short steps	Weakness Parkinson disease or related condition

Asymmetry	Cerebrovascular accident Focal pain or arthritis
Wide-based gait	Fear, balance problems
Flexed knees	Contractures, quadriceps weakness
Slow gait	Fear of falling, weakness, deconditioning, peripheral vascular disease, chronic obstructive pulmonary disease, congestive heart failure, angina

Causes of Falls

Balance and ambulation require a complex interplay of cognitive, neuromuscular, and cardiovascular function. With age, balance mechanisms can become compromised and postural sway increases. These changes predispose the older person to a fall when challenged by an additional insult to any of these systems.

A fall may be the clinical manifestation of an occult problem, such as pneumonia or myocardial infarction, but much more commonly falls are due to the interaction between an impaired patient and an environmental risk factor. Falls in older people are rarely due to a single cause, and effective intervention entails a comprehensive assessment of the patient's intrinsic deficits (usually diseases and medications), the activity engaged in at the time of the fall, and environmental obstacles.

Intrinsic deficits are those that impair sensory input, judgment, blood pressure regulation, reaction time, and balance and gait. Dizziness may be closely related to the deficits associated with falls and gait abnormalities. While it may be impossible to isolate a sole "cause" or a "cure" for falls, gait abnormalities, or dizziness, it is often possible to identify and ameliorate some of the underlying contributory conditions and improve the patient's overall function.

As for most geriatric conditions, medication use is one of the most common, significant, and reversible causes of falling. Benzodiazepines, sedative-hypnotics, cardiac medications, antidepressants, neuroleptics, and the use of multiple medications simultaneously have been associated with an increased fall risk. Other often overlooked but treatable contributors include postural hypotension, (particularly postprandial, which peaks 30–60 minutes after a meal), insomnia, and urinary urgency.

Since most falls occur in or around the home, a visit by a visiting nurse, physical therapist, or health care provider reaps substantial benefits in identifying environmental obstacles and is generally reimbursed by third-party payers, including Medicare.

Complications of Falls

The most common fractures resulting from falls are of the wrist, hip, and vertebrae. There is a high mortality rate (approximately 20% in 1 year) in elderly women with hip fractures, particularly if they were debilitated prior to the time of the fracture.

Fear of falling again is a common, serious, but treatable factor in the elderly person's loss of confidence and independence. Referral to a physical therapist for gait training with special devices is often all that is required.

Chronic subdural hematoma is an easily overlooked complication of falls that must be considered in any elderly patient presenting with new neurologic symptoms or signs. Headache or known history of trauma may both be absent.

Patients who are unable to get up from a fall are at risk for dehydration, electrolyte imbalance, pressure sores, rhabdomyolysis, and hypothermia.

Prevention & Management

The risk of falling and consequent injury, disability, and potential institutionalization can be reduced by modifying those factors outlined in Table 4–4. Emphasis is placed on treating all contributory medical conditions (eg, peripheral edema, delirium), minimizing environmental hazards, and reducing the number of medications—particularly those that induce orthostasis and parkinsonism (eg, -blockers, nitrates, antipsychotics). Also important are strength, balance, and gait training as well as screening and treatment for osteoporosis, if present. There is evidence that vitamin D at doses of 800 international units daily or higher may help prevent falls and fractures. The recommended dose for vitamin D is 800–1000 international units daily for most elders who have no contraindications.

Table 4–4. Fall risk factors and targeted interventions.

Risk Factor	**Targeted Intervention**
Postural hypotension (> 20 mm Hg drop in systolic blood pressure, or systolic blood pressure < 90 mm Hg)	Behavioral recommendations, such as hand clenching, elevation of head of bed; discontinuation or substitution of high-risk medications
Use of benzodiazepine or sedative-hypnotic agent	Education about sleep hygiene; discontinuation or substitution of medications
Use of multiple prescription medications	Review of medications
Environmental hazards	Appropriate changes; installation of safety equipment (eg, grab bars)
Gait impairment	Gait training, assistive devices,

	balance or strengthening exercises
Impairment in transfer or balance	Balance exercises, training in transfers, environmental alterations (eg, grab bars)
Impairment in leg or arm muscle strength or limb range of motion	Exercise with resistance bands or putty, with graduated increases in resistance

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*: Screening.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*: Prevention.

Assistive devices, such as canes and walkers, are useful for many older adults but are often used incorrectly. Canes should be used on the "good" side. The height of walkers and canes should generally be about the level of the wrist. Physical therapists are invaluable in assessing the need for an assistive device, selecting the best device, and training a patient in its correct use.

Patients with repeated falls are often reassured by the availability of phones at floor level, a portable phone, or a lightweight radio call system. Their therapy should also include training in techniques for arising after a fall. The clinical utility of anatomically designed external hip protectors in reducing fractures is currently uncertain.

When to Refer

Patients with a recent history of falls should be referred for physical therapy, eye examination, and home safety evaluation.

When to Admit

If the patient has new falls that are unexplained, particularly in combination with a change in the physical examination, hospitalization should be considered.

Urinary Incontinence

Essentials of Diagnosis

- Involuntary loss of urine.
- *Stress* incontinence: leakage of urine upon coughing, sneezing, or standing.
- *Urge* incontinence: urgency and inability to delay

urination.
- Overflow incontinence may have variable presentation.

General Considerations

Incontinence in older adults is common, and interventions can improve most patients. Many patients fail to tell their providers about it. A simple question about involuntary leakage of urine is a reasonable screen: "Do you have a problem with urine leaks or accidents?"

Classification

Because continence requires adequate mobility, mentation, motivation, and manual dexterity, problems outside the bladder often result in geriatric incontinence. In general, the authors of this chapter find it useful to differentiate between "transient" or "potentially reversible" causes of incontinence and more "established" causes.

Transient Causes

Use of the mnemonic "DIAPPERS" may be helpful in remembering the categories of transient incontinence.

Delirium

A clouded sensorium impedes recognition of both the need to void and the location of the nearest toilet.

Delirium is the most common cause of incontinence in hospitalized patients; once it clears, incontinence usually resolves.

Infection

Symptomatic urinary tract infection commonly causes or contributes to urgency and incontinence. Asymptomatic bacteriuria does not.

Atrophic urethritis or vaginitis

Atrophic urethritis can usually be diagnosed presumptively by the presence of vaginal mucosal telangiectasia, petechiae, erosions, erythema, or friability. Urethral inflammation, if symptomatic, may contribute to incontinence in some women. Some experts suggest a trial of topical estrogen in these cases.

Pharmaceuticals

Drugs are one of the most common causes of transient incontinence. Typical offending agents include potent diuretics, anticholinergics, psychotropics, opioid analgesics, -blockers (in women), agonists (in men), and calcium channel blockers.

Psychological factors

Severe depression with psychomotor retardation may impede the ability or motivation to reach a toilet.

Excess urinary output

Excess urinary output may overwhelm the ability of an older person to reach a toilet in time. In addition to diuretics, common causes include excess fluid intake; metabolic abnormalities (eg, hyperglycemia, hypercalcemia, diabetes insipidus); and disorders associated with peripheral edema, with its associated heavy nocturia when previously dependent legs assume a horizontal position in bed.

Restricted mobility

(See Immobility section, above.) If mobility cannot be improved, access to a urinal or commode (eg, at the bedside) may improve continence.

Stool impaction

This is a common cause of urinary incontinence in hospitalized or immobile patients. Although the mechanism is still unknown, a clinical clue to its presence is the onset of both urinary and fecal incontinence. Disimpaction usually restores urinary continence.

Established Causes

Causes of established incontinence should be addressed after the transient causes have been uncovered and managed appropriately. Risk factors for incontinence include older age, female gender, increased body mass index, and limited physical activity.

Detrusor overactivity (urge incontinence)

Detrusor overactivity refers to uninhibited bladder contractions that cause leakage. It is the most common cause of established geriatric incontinence, accounting for two-thirds of cases, and is usually idiopathic. Women will complain of urinary leakage after the onset of an intense urge to urinate that cannot be forestalled. In men the symptoms are similar, but detrusor overactivity commonly coexists with urethral obstruction from benign prostatic hyperplasia. Because detrusor overactivity also may be due to bladder stones or tumor, the abrupt onset of otherwise unexplained urge incontinence—especially if accompanied by perineal or suprapubic discomfort or sterile hematuria—should be investigated by cystoscopy and cytologic examination of a urine specimen.

Urethral incompetence (stress incontinence)

Urethral incompetence is the second most common cause of established urinary incontinence in older women. Stress incontinence is most commonly seen in men after radical prostatectomy. Stress incontinence is characterized by instantaneous leakage of urine in response to a stress maneuver. It commonly coexists with detrusor overactivity. Typically, urinary loss occurs with laughing, coughing, or lifting heavy objects. Leakage is worse or occurs only during the day, unless another abnormality (eg, detrusor overactivity) is also present. To test for stress incontinence, have the patient relax her perineum and cough vigorously (a single cough) while standing with a full bladder. Instantaneous leakage indicates stress incontinence if urinary retention has been excluded by postvoiding residual determination using ultrasound. A delay of several seconds or persistent leakage suggests that the problem is instead caused by an uninhibited bladder contraction induced by coughing.

Urethral obstruction

Urethral obstruction (due to prostatic enlargement, urethral stricture, bladder neck contracture, or prostatic cancer) is a common cause of established incontinence in older men but is rare in older women. It can present as dribbling incontinence after voiding, urge incontinence due to detrusor overactivity (which coexists in two-thirds of cases), or overflow incontinence due to urinary retention. Renal ultrasound is required to exclude hydronephrosis in men whose postvoiding residual urine exceeds 150 mL.

Detrusor underactivity (overflow incontinence)

Detrusor underactivity is the least common cause of incontinence. It may be idiopathic or due to sacral lower motor nerve dysfunction. When it causes incontinence, detrusor underactivity is associated with urinary frequency, nocturia, and frequent leakage of small amounts. The elevated postvoiding residual urine (generally over 450 mL) distinguishes it from detrusor overactivity and stress incontinence, but only urodynamic testing differentiates it from urethral obstruction in men. Such testing usually is not required in women, in whom obstruction is rarely present.

Treatment

Transient Causes

Each identified transient cause should be treated regardless of whether an established cause coexists. For patients with urinary retention induced by an anticholinergic agent, discontinuation of the drug should first be considered. If this is not feasible, substituting a less anticholinergic agent (eg, sertraline instead of desipramine for depression) may be useful.

Established Causes

Detrusor overactivity

The cornerstone of treatment is bladder training. Patients start by voiding on a schedule based on the shortest interval recorded on a bladder record. They then gradually lengthen the interval between voids by 30 minutes each week using relaxation techniques to postpone the urge to void. For cognitively impaired patients who are unable to manage on their own, timed voiding initiated by caregivers is an alternative.

Pelvic floor muscle ("Kegel") exercises, with or without biofeedback, can reduce the frequency of incontinence episodes when performed correctly and sustained. If behavioral approaches prove insufficient, drug therapy with antimuscarinic agents may provide additional benefit. The two oral drugs for which there is the most experience are tolterodine and oxybutynin. Available regimens of these drugs follow: short-acting tolterodine, 1–2 mg twice a day; long-acting tolterodine, 2–4 mg daily; short-acting oxybutynin, 2.5–5 mg twice or three times a day; long-acting oxybutynin, 5–15 mg daily; and oxybutynin transdermal patch, 3.9 mg per day applied twice weekly. All of these agents can produce delirium, dry mouth, or urinary retention; long-acting preparations may be better tolerated. Newer agents such as trospium chloride (20 mg orally once or twice daily), darifenacin (7.5–15 mg orally daily), and solifenacin (5–10 mg orally daily) appear to have similar efficacy and are reported to be better tolerated than oxybutynin and tolterodine, but limited data exist in older patients.

The combination of behavioral therapy and antimuscarinics appears to be more effective than either alone.

In men with both benign prostatic hyperplasia and detrusor overactivity, an antimuscarinic agent may provide relief over an -agonist alone but should not be prescribed to men with an elevated postvoid residual urine volume (ie, > 200 mL) because of the risk of causing acute urinary retention.

Urethral incompetence (stress incontinence)

Lifestyle modifications, including limiting caffeine intake and timed voiding, may be helpful for some women, particularly women with mixed stress/urge incontinence. Pelvic floor muscle exercises are effective for women with mild to moderate stress incontinence who wish to avoid surgery and who can use them indefinitely; the exercises can be combined, if necessary, with biofeedback, electrical stimulation, or vaginal cones. Pelvic floor muscle exercises can be taught during bimanual vaginal examination or by asking the patient to try to contract the muscle that they use to stop the flow of urine. It is often necessary to perform 30–60 exercises daily for 6 weeks before significant improvement will be noticed. Pessaries or vaginal cones may be helpful in some women but should be prescribed by providers who are experienced with using these modalities.

Although a last resort, surgery is the most effective treatment for stress incontinence, resulting in a cure rate of 75–85% even in older women. Drug therapy is limited. Several trials have shown that duloxetine, a serotonin and norepinephrine reuptake inhibitor, reduces stress incontinence episodes in women. It is approved for use for this indication in some countries but not the United States. Side effects, including nausea, are common.

Urethral obstruction

Surgical decompression is the most effective treatment for obstruction, especially in the setting of urinary retention due to benign prostatic hyperplasia. A variety of newer, less invasive techniques make decompression feasible even for frail men. For the nonoperative candidate with urinary retention, intermittent or indwelling catheterization is used. For a man with prostatic obstruction who does not require or desire immediate surgery, treatment with -blocking agents (eg, terazosin, 1–10 mg daily; prazosin, 1–5 mg orally twice daily; tamsulosin, 0.4–0.8 mg daily) can improve symptoms and delay obstruction. Finasteride, 5 mg daily, can provide additional benefit to an -blocking agent in men with an enlarged prostate. The potential for finasteride to reduce the risk of prostate cancer is under investigation.

Detrusor underactivity

For the patient with a poorly contractile bladder, augmented voiding techniques (eg, double voiding, suprapubic pressure) often prove effective. If further emptying is needed, intermittent or indwelling catheterization is the only option. Antibiotics should be used only for symptomatic upper urinary tract infection or as prophylaxis against recurrent symptomatic infections in a patient using intermittent catheterization; they should not be used as prophylaxis with an indwelling catheter.

When to Refer

- Men with urinary obstruction who do not respond to medical therapy should be referred to a urologist.
- Women who do not respond to medical and behavioral therapy should be referred to a urogynecologist or urologist.

Undernutrition & Frailty

General Considerations

Undernutrition affects substantial numbers of elderly persons and may be the clinical trigger that prompts the label of "failure to thrive." The degree of unintended weight loss that deserves evaluation is not agreed upon, although a reasonable threshold is loss of 5% of body weight in 1 month or 10% of body weight in 6 months.

"Frailty" is a term that may be clinically useful for describing a subgroup of patients—almost always elders—who have decreased functional reserve. Common clinical features of frailty include weakness, slowness, weight loss, low activity, and fatigue. Frailty may be accompanied by physiologic changes in inflammatory and neuroendocrine systems. The label of "failure to thrive" is typically applied when some triggering event—loss of social support, a bout of depression or pneumonia, the addition of a new medication—pulls a struggling elderly person below the threshold of successful independent living.

Clinical Findings

Useful laboratory and radiologic studies for the patient with weight loss or "failure to thrive" include complete blood count, serum chemistries (including glucose, TSH, creatinine, calcium), urinalysis, and chest radiograph. Exploring the patient's social situation, cognition, mood, and dental health are at least as important as looking for a purely medical cause of weight loss. These studies are intended to uncover an occult metabolic or neoplastic cause but are not exhaustive.

Treatment

Oral nutritional supplements of 200–1000 kcal/d can increase weight and improve outcomes in malnourished hospitalized elders. Megestrol acetate as an appetite stimulant has not been shown to increase body mass or lengthen life in the elderly population.

For those who have lost the ability to feed themselves, assiduous hand feeding may allow maintenance of weight. Although artificial nutrition and hydration ("tube feeding") may seem a more convenient alternative, it deprives the patient of the taste and texture of food as well as the social milieu typically associated with mealtime; before this option is chosen, the patient or his or her surrogate will wish to review the benefits and burdens of the treatment in light of overall goals of care. If the patient makes repeated attempts to pull out the tube during a trial of artificial nutrition, the treatment burden becomes substantial, and the utility of tube feeding should be reconsidered. Although commonly used, there is no evidence that tube feeding prolongs life in patients with end-stage dementia.

The ideal strategies for diagnosing and managing "frailty" or "failure to thrive" are uncertain but are usually supportive, multifactorial, and individualized based on patient goals, life expectancy, and comorbidities. Sometimes, transitioning a patient to a palliative approach or a hospice program is the most appropriate clinical intervention.

Milne AC et al. Meta-analysis: Protein and energy supplementation in older people. Ann Intern Med. 2006 Jan 3;144(1):37–48. [PMID: 16389253]

Pressure Ulcers

Essentials of Diagnosis

- Examine at-risk patients on admission to hospital and daily thereafter.
- Pressure ulcers should be described by one of six stages:

  – Blanchable hyperemia (stage I).
  – Extension through epidermis (stage II).
  – Full thickness skin loss (stage III).
  – Full thickness wounds with extension into muscle, bone, or supporting structures (stage IV).
  – If eschar or slough overlies the wound, the wound

is unstageable.
– Suspected deep tissue injury is an area of discolored or blistered skin.

General Considerations

The majority of pressure ulcers develop during a hospital stay for an acute illness. Incident rates range from 3% to 30% and vary according to patient characteristics. The primary risk factor for pressure ulcers is immobility. Other contributing risk factors include reduced sensory perception, moisture (urinary and fecal incontinence), poor nutritional status, and friction and shear forces.

In 2007, the National Pressure Ulcer Advisory Panel added two stages to the original four pressure ulcer stages: suspected deep tissue injury and unstageable. Ulcers in which the base is covered by slough (yellow, tan, gray, green or brown) and/or eschar (tan, brown or black) are considered unstageable. Suspected deep tissue injury is an area of purple or maroon discolored intact skin or blood-filled blister. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer or cooler compared with adjacent tissue.

A number of risk assessment instruments including the Braden Scale and the Norton score can be used to assess the risk of developing pressure ulcers; both have reasonable performance characteristics. These instruments can be used to identify the highest risk patients who might benefit most from scarce resources such as mattresses that reduce or relieve pressure.

As of October 2008, Medicare will no longer reimburse for hospital-acquired pressure ulcers. Pressure ulcers present on admission will qualify for a higher reimbursement. The medical record must contain documentation of pressure ulcers present on admission, and coders are required to use physician documentation as the basis for coding and reporting; therefore, physicians should include a full skin assessment on every admission history and physical.

Prevention

Using specialized support surfaces (including mattresses, beds, and cushions), patient repositioning, optimizing nutritional status, and moisturing sacral skin are strategies that have been shown to reduce pressure ulcers. For moderate- to high-risk patients, mattresses or overlays that reduce tissue pressure below a standard mattress appear to be superior to standard mattresses. The literature comparing specific products is sparse and inconclusive.

Evaluation

Evaluation of pressure ulcers should include patient's risk factors and goals of care, wound stage, size, depth, presence or absence of exudate, type of exudate present, appearance of the wound bed, and whether there appears to be surrounding infection, sinus tracking, or cellulitis. In poorly healing or atypical pressure ulcers, biopsy should be performed to rule out malignancy or other less common lesions such as pyoderma gangrenosum.

Treatment

Treatment is aimed toward removing necrotic debris and maintaining a moist wound bed that will promote healing and formation of granulation tissue. The type of dressing that is recommended depends on the location and depth of the wound, whether necrotic tissue or dead space is present, and the amount of exudate (Table 4–5). Pressure-reducing devices (eg, air-fluid beds and low air loss beds) are associated with improved healing rates. Although poor nutritional status is a risk factor for the development of pressure ulcers, the results of trials of nutritional supplementation in the treatment of pressure ulcers have been disappointing.

Table 4–5. Treatment of pressure ulcers.

Ulcer Type	**Dressing Type and Considerations**
Stage I and suspected deep tissue injury	Polyurethane film Hydrocolloid wafer Semipermeable foam dressing

Stage II	Hydrocolloid wafers Semipermeable foam dressing Polyurethane film
Stage III/IV	For highly exudative wounds, use highly absorptive dressing or packing, such as calcium alginate Wounds with necrotic debris must be debrided Debridement can be autolytic, mechanical (wet to moist), or surgical Shallow, clean wounds can be dressed with hydrocolloid wafers, semipermeable foam, or polyurethane Deep wounds can be packed with gauze; if the wound is deep and highly exudative, an absorptive packing should be used
Heel ulcer	Do not remove eschar on heel ulcers because it can help promote healing (eschar in other locations should be débrided)
Unstageable	Debride before deciding on further therapy

Providers can become easily overwhelmed by the array of products available for treatment of established pressure ulcers. Most institutions should designate a wound care expert or wound care team to select a streamlined wound care product line that has simple guidelines. In a patient with end-stage disease who is receiving palliative care, appropriate treatment might be directed toward comfort (including minimizing dressing changes and odors) rather than efforts directed at healing.

Complications

Pressure ulcers are associated with increased mortality rates, although a causal link has not been proven. Complications include pain, cellulitis, osteomyelitis, systemic sepsis, and prolongation of lengths of stay in the inpatient or nursing home setting.

When to Refer

Ulcers that are large or nonhealing should be referred to a plastic or general surgeon or dermatologist for biopsy, debridement, and possible skin grafting.

When to Admit

Patients with pressure ulcers should be admitted if the primary residence is unable to provide adequate wound care or pressure reduction, if the wound is infected, or for complex or surgical wound care.

Pharmacotherapy & Polypharmacy

There are several reasons for the greater incidence of iatrogenic drug reactions in the elderly population, the most important of which is the high number of medications that are taken by elders, especially those with multiple comorbidities. Drug metabolism is often impaired in this group due to a decrease in glomerular filtration rate, as well as reduced hepatic clearance. The latter is due to decreased activity of microsomal enzymes and reduced hepatic perfusion with aging. The volume of distribution of drugs is also affected. Since older adults have a decrease in total body water and a relative increase in body fat, water-soluble drugs become more concentrated and fat-soluble drugs have longer half-lives.

Older individuals often have varying responses to a given serum drug level. Thus, they are more sensitive to some drugs (eg, opioids) and less sensitive to others (eg, -blocking agents).

Precautions in Administering Drugs

Nonpharmacologic interventions can often be a first-line alternative to drugs (eg, diet for mild hypertension or type 2 diabetes mellitus).

Therapy is begun with less than the usual adult dosage and the dosage increased slowly, consistent with its pharmacokinetics in older patients. However, age-related changes in drug distribution and clearance are variable among individuals, and some require full doses. After determining acceptable measures of success and toxicity, the dose is increased until one or the other is reached.

Despite the importance of beginning new drugs in a slow, measured fashion, all too often an inadequate trial is attempted (in terms of duration or dose) before discontinuation. Antidepressants, in particular, are frequently stopped before therapeutic dosages are reached.

A number of simple interventions can help improve adherence to the prescribed medical regimen. When possible, the provider should keep the dosing schedule simple, the number of pills low, the medication changes as infrequent as possible, and encourage the patient to use a single pharmacy. Pillboxes or "medi-sets" help some patients with adherence.

Having the patient or caregiver bring in all medications at each visit can help the provider perform medication reconciliation and reinforce reasons for drug use, dosage, frequency of administration, and possible adverse effects. Medication reconciliation is particularly important if the patient sees multiple providers.

Although serum drug levels may be useful for monitoring certain drugs with narrow therapeutic windows (eg, digoxin), toxicity can still occur even with "normal" therapeutic levels of many drugs. The risk of toxicity goes up with the number of medications prescribed. Certain combinations of medications (eg, warfarin and many types of antibiotics, digoxin and clarithromycin, angiotensin-converting enzyme inhibitors and NSAIDs) are particularly likely to cause drug-drug interactions, and should be watched carefully.

Trials of individual drug discontinuation should be considered (including sedative-hypnotics, antipsychotic medications, digoxin, proton pump inhibitors, NSAIDs) when the original indication is unclear, the goals of care have changed, or the patient might be experiencing side effects.

The Medicare prescription drug benefit in the United States certainly helps many elders with burdensome prescription drug costs. However, its benefits are complex and difficult to understand, particularly for those elders with limited cognition, literacy, and Internet access. Reforms are being debated in Congress that could alter the benefits. Information is available at http://www.medicare.gov.

When to Refer

Patients with poor or uncertain adherence may benefit from referral to a pharmacist or a home health nurse.

Pham CB et al. Minimizing adverse drug events in older patients. Am Fam Physician. 2007 Dec 15;76(12):1837–44. [PMID: 18217523]

Vision Impairment

Although visual loss is not severe in many elders, visual impairment is an independent risk factor for falls; it also has a significant impact on quality of life. The prevalence of serious and correctable visual disorders in elders is sufficient to warrant a complete eye examination by an ophthalmologist or optometrist annually or biannually for most elders. Many patients with visual loss benefit from a referral to a low vision program, and primary care providers should not assume that an ophthalmologist or optometrist will automatically make this referral.

Rosenberg EA et al. The visually impaired patient. Am Fam Physician. 2008 May 15;77(10):1431–6. [PMID: 18533377]

Hearing Impairment

Over one-third of persons over age 65 and half of those over age 85 have some hearing loss. This deficit is correlated with social isolation and depression. A reasonable screen is to ask patients if they have hearing impairment. Those who answer "yes" should be referred for audiometry. Those who answer "no" may still have hearing impairment and can be screened by a handheld audioscope or the whispered voice test. The whispered voice test is administered by standing 2 feet behind the subject, whispering three random numbers, and simultaneously rubbing the external auditory canal of the non-tested ear to mask the sound. If the patient is unable to identify all three numbers, the test should be repeated with different numbers, and if still abnormal, a referral should be made to audiometry. To determine the degree to which hearing impairment interferes with functioning, the provider may ask if the patient becomes frustrated when conversing with family members, is embarrassed when meeting new people, has difficulty watching TV, or has problems understanding conversations. Caregivers or family members often have important information on the impact of hearing loss on the patient's social interactions.

Compliance with hearing amplification can be a challenge because of the stigma associated with hearing aid use as well as the cost of such devices, which are not paid for under most Medicare plans. Special telephones, amplifiers for the television, and many other devices are available to aid the person with hearing loss. Portable amplifiers are pager-sized units with earphones attached; they can be purchased inexpensively at many electronics stores and can be useful in health care settings for improving communication with hearing impaired patients. In general, facing the patient and speaking slowly in a low tone is a more effective communication strategy than yelling.

Folate supplementation was found to slow age-associated hearing loss in a country without widespread dietary folate fortification; it is unknown whether this practice is beneficial in countries that practice folate fortification.

Durga J et al. Effects of folic acid supplementation on hearing in older adults: a randomized, controlled trial. Ann Intern Med. 2007 Jan 2;146(1):1–9. [PMID: 17200216]

Elder Abuse

According to the best available estimates, between 1 and 2 million Americans age 65 or older have been injured, exploited, or otherwise mistreated by someone on whom they depended for care or protection. Neglect, both by self and caregiver, are the most common forms of abuse, followed by financial and emotional abuse.

Clues to the possibility of elder abuse include behavioral changes in the presence of the caregiver, delays between occurrence of injuries and sought treatment, inconsistencies between an observed injury and associated explanation, lack of appropriate clothing or hygiene, and not filling prescriptions. Many elders with cognitive impairment become targets of financial abuse.

It is helpful to observe and talk with every older person alone for at least part of a visit in order to question directly about possible abuse and neglect (Table 4–6). The laws in most states require health care providers to report suspected abuse or neglect. Adult protective services (APS) agencies are available in all 50 states to assist in cases of suspected elder abuse. The Web site for National Center for Elder Abuse is http://www.ncea.aoa.gov.

Table 4–6. Questions that may elicit a history of elder

abuse.
1. Has anyone ever hurt you?
2. Has anyone ever touched you without your consent?
3. Has anyone ever made you do things you didn't want to do?
4. Has anyone taken anything of yours without asking?
5. Has anyone ever scolded or threatened you?
6. Have you signed any papers that you didn't understand?
7. Is there anyone at home you are fearful of?
8. Are you alone much?
9. Has anyone ever refused to help you take care of yourself when you needed help?

Definition & Scope of Palliative Care

The focus of palliative care is to improve symptoms and quality of life at any stage of illness, utilizing the expertise of an interdisciplinary team. At the end of life, palliative care often becomes the only focus of care, but a palliative care approach is beneficial throughout the course of serious chronic and terminal illnesses, regardless of prognosis, whether the goal is to cure disease or manage chronic illness.

The World Health Organization defines palliative care as "an approach that improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual." Palliative care commonly involves management of pain and other symptoms, including dyspnea, nausea and vomiting, constipation, and agitation; emotional distress, such as depression, anxiety, and interpersonal strain; and existential distress, such as spiritual crisis. While palliative care has been recognized formally as a medical subspecialty by the American Board of Medical Specialties and palliative care experts are increasingly available in hospital and outpatient settings, all clinicians should possess the basic skills to be able to manage pain; treat dyspnea; identify possible depression; communicate about important issues, such as prognosis and patient preferences for care; and help address spiritual distress.

Symptoms that cause significant suffering are a medical emergency that should be managed aggressively with frequent elicitation, continuous reassessment, and individualized treatment. While patients at the end of life may experience a host of distressing symptoms, pain, dyspnea, and delirium are among the most feared and burdensome. The palliation of these common symptoms is described later in this chapter. The principles of palliative care dictate that properly informed patients or their surrogates may decide to pursue aggressive symptom relief at the end of life even if, as a known but unintended consequence, the treatments preclude further unwanted curative interventions or even hasten death. There is a growing awareness that scrupulous symptom control for patients with end-stage illness may even prolong life.

Principles of Pain Management

The experience of pain includes the patient's emotional reaction to it and is influenced by many factors, including the patient's prior experiences with pain, meaning given to the pain, emotional stresses, and family and cultural influences. Pain is a subjective phenomenon, and clinicians cannot reliably detect its existence or quantify its severity without asking the patient directly. A useful means of assessing pain and evaluating the effectiveness of analgesia is to ask the patient to rate the degree of pain along a numeric or visual pain scale (Table 5–1).

Table 5–1. Pain assessment scales.
A. Numeric Rating Scale

B. Numeric Rating Scale Translated into Word and Behavior Scales

Pain intensity	**Word scale**	**Nonverbal behaviors**
0	No pain	Relaxed, calm expression
1–2	Least pain	Stressed, tense expression
3–4	Mild pain	Guarded movement, grimacing
5–6	Moderate pain	Moaning, restless
7–8	Severe pain	Crying out
9–10	Excruciating pain	Increased intensity of above

C. Wong Baker FACES Pain Rating Scale[1]

0 No hurt	1 Hurts Little Bit	2 Hurts Little More	3 Hurts Even More	4 Hurts Whole Lot	5 Hurts Worst

D, Winkelstein ML. *Wong's Essentials of Pediatric Nursing,* ed. 7. Copyright, Mosby.

General guidelines for management of pain are recommended for the treatment of all patients with pain (Table 5–2). Clinicians should ask about the nature, severity, timing, location, quality, and aggravating and relieving factors of the pain. Distinguishing between somatic, visceral, and neuropathic pain is essential to proper tailoring of pain treatments. The goal of pain management is properly decided by the patient. Some patients may wish to be completely free of pain even at the cost of significant sedation, while others will wish to control pain to a level that still allows maximal functioning.

Table 5–2. Recommended clinical approach to pain management.
Ask about pain regularly. Assess pain systematically (quality, description, location, intensity or severity, aggravating and ameliorating factors, cognitive responses). Ask about goals for pain control, management preferences.
Believe the patient and family in their reports of pain and what relieves it.
Choose pain control options appropriate for the patient,

family, and setting. Consider drug type, dosage, route, contraindications, side effects. Consider nonpharmacologic adjunctive measures.
Deliver interventions in a timely, logical, coordinated manner.
Empower patients and their families. Enable patients to control their course to the greatest extent possible.
Follow up to reassess persistence of pain, changes in pain pattern, development of new pain.

Adapted from Jacox AK et al: *Management of Cancer Pain: Quick Reference Guide No. 9.* AHCPR Publication No. 94–0593. Rockville, MD: Agency for Health Care Policy and Research, Public Health Service, U.S. Department of Health and Human Services. March 1994.

Chronic severe pain should be treated continuously. For ongoing pain, a long-acting analgesic can be given around the clock with a short-acting medication as needed for "breakthrough" pain. For patients near the end of life, the oral route of administration is preferred because it is easier to administer at home, is not painful, and imposes no risk from needle exposure. Rectal, transdermal, and subcutaneous administration are also frequently used, as is intravenous or, rarely, intrathecal administration when necessary. Patient-controlled analgesia (PCA) of intravenous medications can provide better analgesia with less medication use and its principles have been adapted for use with oral administration.

When possible, the underlying cause of pain should be diagnosed and treated, balancing the burden of diagnostic tests with the patient's suffering. Treating the underlying cause of pain, such as radiation therapy for painful bone metastases, can obviate the need for ongoing treatment with analgesics along with their side effects. Regardless of decisions about seeking and treating its underlying cause, every patient should be offered prompt relief of pain.

Pain at the End of Life

Definition & Prevalence

Pain is a common problem for patients at the end of life—up to 75% of patients dying of cancer experience pain—and it is what many people say they fear most about dying. Pain is also a common complaint among patients with noncancer diagnoses and is routinely undertreated. Up to 50% of severely ill hospitalized patients spent half of their time during the last 3 days of life in moderate to severe pain. The Joint Commission now includes pain management standards for all patient care organizations that it accredits.

Barriers to Good Care

Deficiencies in pain management at the end of life have been documented in many settings. Some clinicians refer pain management to others when they believe that a patient's pain is not due to the disease for which they are treating the patient. Even oncologists often misperceive the origin of their patients' pain and inappropriately ignore complaints of pain.

Many clinicians have limited training and clinical experience with pain management and thus are understandably reluctant to attempt to manage severe pain. Lack of knowledge about the proper selection and dosing of analgesic medications carries with it attendant and typically exaggerated fears about the side effects of pain medications, including the possibility of respiratory depression from opioids. Most clinicians, however, can develop good pain management skills, and nearly all pain, even at the end of life, can be managed without hastening death through respiratory depression. In rare instances, palliative sedation may be necessary to control intractable agony as an intervention of last resort.

A misunderstanding of the physiologic effects of opioids can lead to unfounded concerns on the part of clinicians, patients, or family members that patients will become addicted to opioids. While physiologic **tolerance** (requiring increasing dosage to achieve the same analgesic effect) and **dependence** (requiring continued dosing to prevent symptoms of medication withdrawal) are expected with regular opioid use, the use of opioids at the end of life for relief of pain and dyspnea is not generally associated with a risk of psychological **addiction** (misuse of a substance for purposes other than one for which it was prescribed and despite negative consequences in health, employment, or legal and social spheres). The risk for problematic use of pain medications is higher, however, in patients with a history of addiction. Yet even patients with such a history need pain relief, albeit with closer monitoring. Some patients who demonstrate behaviors associated with addiction (demand for specific medications and doses, anger and irritability, poor cooperation or disturbed interpersonal reactions) may have **pseudo-addiction,** defined as exhibiting behaviors associated with addiction but only because their pain is inadequately treated. Once pain is relieved, these behaviors cease. In all cases, clinicians must be prepared to use appropriate doses of opioids in order to relieve distressing symptoms for patients at the end of life.

Some clinicians fear legal repercussions from prescribing the high doses of opioids sometimes necessary to control pain at the end of life. Some states have enacted special licensing and documentation requirements for opioid prescribing. However, governmental and professional medical groups, regulators, and the US Supreme Court have made it clear that appropriate treatment of pain is the right of the patient and a fundamental responsibility of the clinician. In fact, clinicians have been successfully sued for undertreatment of pain. Although clinicians may feel trapped between consequences of over- or under-prescribing opioids, there remains a wide range of practice in which clinicians can appropriately treat pain. Referral to pain or palliative care experts is appropriate whenever pain cannot be controlled expeditiously by the primary clinician.

Pharmacologic Pain Management Strategies

In general, pain can be well controlled with analgesic medications—both opioid and nonopioid—at any stage of illness. Evidence-based summaries and guidelines are available from the Agency for Healthcare Research and Quality (http://www.ncbi.nlm.nih.gov/books/bv.fcgi?rid=hstat1.chapter.86205) and other organizations (http://www.nccn.org/professionals/physician_gls/PDF/pain.pdf). For mild to moderate pain, acetaminophen, aspirin, and nonsteroidal anti-inflammatory drugs (NSAIDs) may be sufficient. For moderate to severe pain, these agents combined with opioids may be helpful. Severe pain typically requires opioids.

Acetaminophen & NSAIDs

Appropriate doses of acetaminophen may be just as effective an analgesic and antipyretic as NSAIDs but without the risk of gastrointestinal bleeding or ulceration.

Acetaminophen can be given at a dosage of 500–1000 mg orally every 6 hours, although it can be taken every 4 hours as long as the risk of hepatotoxicity is kept in mind. Hepatotoxicity is a concern at doses greater than 4 g/d long-term, and doses for older patients and those with liver disease should not exceed 2 g/d.

Aspirin (325–650 mg orally every 4 hours) is an effective analgesic, antipyretic, and anti-inflammatory medication. Gastrointestinal irritation and bleeding, bleeding from other sources, allergy, and an association with Reye syndrome in children and teenagers limit its use.

Commonly used NSAIDs and their dosages are listed in Table 5–3. Like aspirin, the other NSAIDs are antipyretic, analgesic, and anti-inflammatory. NSAIDs increase the risk of gastrointestinal bleeding by 1.5 times normal. The risks of bleeding and nephrotoxicity from NSAIDs are both increased in elders. Gastrointestinal bleeding and ulceration may be prevented with the concurrent use of proton pump inhibitors (eg, omeprazole, 20–40 mg orally daily) or with the class of NSAIDs that inhibit only cyclooxygenase (COX)-2. Because of concerns about an association of COX-2 inhibitors with an increased risk of myocardial infarction, only celecoxib is still available. Celecoxib (100 mg/d to 200 mg orally twice daily) should be used with caution in patients with cardiac disease. The NSAIDs, including COX-2 inhibitors, can lead to exacerbations of congestive heart failure and should be used with caution in patients with that condition.

Table 5–3. Acetaminophen, COX-2 inhibitors, and useful nonsteroidal anti-inflammatory drugs.					
Drug	**Usual Dose for Adults 50 kg**	**Usual Dose for Adults < 50 kg**[1]	**Cost per Unit**	**Cost for 30 Days**[2]	**Comments**[3]
Acetaminophen[4] (Tylenol, Datril, etc)	650 mg q4h or 975 mg q6h	10–15 mg/kg q4h (oral); 15–20 mg/kg	$0.02/325 mg (oral) OTC; $0.52/650 mg (rectal) OTC	$7.20 (oral); $93.60 (rectal)	Not an NSAID because it lacks peripheral anti-inflammatory effects. Equivalent to aspirin as

		q4h (rectal)			analgesic and antipyretic agent.
Aspirin[5]	650 mg q4h or 975 mg q6h	10–15 mg/kg q4h (oral); 15–20 mg/kg q4h (rectal)	$0.02/325 mg OTC; $0.31/600 mg (rectal) OTC	$7.20 (oral); $55.80 (rectal)	Available also in enteric-coated form that is more slowly absorbed but better tolerated.
Celecoxib[4] (Celebrex)	200 mg once daily (osteoarthritis); 100–200 mg twice daily (rheumato	100 mg once or twice daily	$2.45/100 mg; $4.02/200 mg	$120.60 OA; $241.20 RA	Cyclooxygenase-2 inhibitor. No antiplatelet effects. Lower doses for elderly

	id arthritis)				who weigh < 50 kg. Lower incidence of endoscopic gastrointestinal ulceration. Not known if true lower incidence of gastrointestinal bleeding. Possible link to cardiovascular toxicity. Celecoxib is contraindicated in sulfonamid

					e allergy.
Choline magnesium salicylate[6] (Trilasate, others)	1000–1500 mg three times daily	25 mg/kg three times daily	$0.46/500 mg	$124.20	Salicylates cause less gastrointestinal distress and kidney impairment than NSAIDs but are probably less effective in pain management than NSAIDs.
Diclofenac (Voltaren, Cataflam, others)	50–75 mg two or three times daily		$0.86/50 mg; $1.04/75 mg	$77.40; $93.60	May impose higher risk of hepatotoxicity. Low incidence of gastrointest

					inal side effects. Enteric-coated product; slow onset.
Diclofenac sustained release (Voltaren-XR, others)	100–200 mg once daily		$2.81/ 100 mg	$168.60	
Diflunisal[7] (Dolobid, others)	500 mg q12h		$1.29/ 500 mg	$77.40	Fluorinated acetylsalicylic acid derivative.
Etodolac (Lodine, others)	200–400 mg q6–8h		$1.47/ 400 mg	$176.40	Perhaps less gastrointestinal toxicity.
Fenoprofen calcium (Nalfon, others)	300–600 mg q6h		$0.51/ 600 mg	$61.20	Perhaps more side effects than others, including

					tubulointerstitial nephritis.
Flurbiprofen (Ansaid)	50–100 mg three or four times daily		$0.79/50 mg; $1.19/100 mg	$94.80; $142.80	Adverse gastrointestinal effects may be more common among elderly.
Ibuprofen (Motrin, Advil, Rufen, others)	400–800 mg q6h	10 mg/kg q6–8h	$0.28/600 mg Rx; $0.05/200 mg OTC	$33.60; $9.00	Relatively well tolerated. Less gastrointestinal toxicity.
Indomethacin (Indocin, Indometh, others)	25–50 mg two to four times daily		$0.38/25 mg; $0.64/50 mg	$45.60; $76.80	Higher incidence of dose-related toxic effects, especially gastrointest

					inal and bone marrow effects.
Ketoprofen (Orudis, Oruvail, others)	25–75 mg q6–8h (max 300 mg/d)		$0.96/50 mg Rx; $1.07/75 mg Rx; $0.09/12.5 mg OTC	$172.80; $128.40; $16.20	Lower doses for elderly.
Ketorolac tromethamine (Toradol)	10 mg q4–6h to a maximum of 40 mg/d orally		$1.02/10 mg	Not recommended	Short-term use (< 5 days) only; otherwise, increased risk of gastrointestinal side effects.
Ketorolac tromethamine[8] (Toradol)	60 mg IM or 30 mg IV initially,		$1.44/30 mg	Not recommended	Intramuscular or intravenous NSAID

	then 30 mg q6h IM or IV				as alternative to opioid. Lower doses for elderly. Short-term use (< 5 days) only.
Magnesium salicylate (various)	467 mg q4h		$0.08/ 467 mg OTC	$9.60	
Meclofenamate sodium[9] (Meclomen)	50–100 mg q6h		$3.40/ 100 mg	$408.00	Diarrhea more common.
Mefenamic acid (Ponstel)	250 mg q6h		$5.85/ 250 mg	$702.00	
Nabumetone (Relafen)	500–1000 mg once daily (max dose 2000		$1.30/ 500 mg; $1.53/ 750	$91.80	May be less ulcerogenic than ibuprofen,

	mg/d)		mg		but overall side effects may not be less.
Naproxen (Naprosyn, Anaprox, Aleve [OTC], others)	250–500 mg q6–8h	5 mg/kg q8h	$1.30/500 mg Rx; $0.08/220 mg OTC	$156.00; $7.20 OTC	Generally well tolerated. Lower doses for elderly.
Oxaprozin (Daypro, others)	600–1200 mg once daily		$1.51/600 mg	$90.60	Similar to ibuprofen. May cause rash, pruritus, photosensitivity.
Piroxicam (Feldene, others)	20 mg daily		$2.64/20 mg	$79.20	Not recommended in the elderly due to high adverse drug reaction

					rate. Single daily dose convenient. Long half-life. May cause higher rate of gastrointestinal bleeding and dermatologic side effects.
Sodium salicylate	325–650 mg q3–4h		$0.08/ 650 mg OTC	$19.20	
Sulindac (Clinoril, others)	150–200 mg twice daily		$0.98/ 150 mg; $1.21/ 200 mg	$58.80; $72.60	May cause higher rate of gastrointestinal bleeding. May have less

					nephrotoxic potential.
Tolmetin (Tolectin)	200–600 mg four times daily		$0.75/200 mg; $1.80/600 mg	$90.00; $216.00	Perhaps more side effects than others, including anaphylactic reactions.

[1] Acetaminophen and NSAID dosages for adults weighing less than 50 kg should be adjusted for weight.

[2] Average wholesale price (AWP, for AB-rated generic when available) for quantity listed. Source: *Red Book* Update, Vol. 28, No. 3, March 2009. AWP may not accurately represent the actual pharmacy cost because wide contractual variations exist among institutions.

[3] The adverse effects of headache, tinnitus, dizziness, confusion, rashes, anorexia, nausea, vomiting, gastrointestinal bleeding, diarrhea, nephrotoxicity, visual disturbances, etc, can occur with any of these drugs. Tolerance and efficacy are subject to great individual variations among patients. Note: All NSAIDs can increase serum lithium levels.

[4] Acetaminophen and celecoxib lack antiplatelet effects.

[5] May inhibit platelet aggregation for 1 week or more and may cause bleeding.

[6] May have minimal antiplatelet activity.

[7] Administration with antacids may decrease absorption.

[8] Has the same gastrointestinal toxicities as oral NSAIDs.

[9] Coombs-positive autoimmune hemolytic anemia has been associated with prolonged use.

OTC, over-the-counter; Rx, prescription; OA, osteoarthritis; RA, rheumatoid arthritis.

Opioid Medications

For many patients, opioids are the mainstay of pain management. Opioids are appropriate for severe pain due to any cause, including neuropathic pain. Opioid medications are listed in Table 5–4. Full opioid agonists such as morphine, hydromorphone, oxycodone, methadone, fentanyl, hydrocodone, and codeine are used most commonly. Hydrocodone and codeine are typically combined with acetaminophen or an NSAID. Short-acting formulations of oral morphine sulfate (starting dosage 4–12 mg orally every 3–4 hours), hydromorphone (1–4 mg orally every 3–4 hours), or oxycodone (5–10 mg orally every 3–4 hours) are useful for acute pain not controlled with other analgesics. These same oral medications, or oral transmucosal fentanyl (200 mcg dissolved in mouth) or buccal fentanyl (100 mcg dissolved in the mouth), can be used for "rescue" treatment for patients experiencing pain that breaks through long-acting medications. For chronic stable pain, long-acting medications are preferred, such as oral sustained-release morphine (one to three times a day) or oxycodone (two or three times a day) or methadone (three or four times a day).

Table 5–4. Useful opioid agonist analgesics.

done[6] (in Percocet, Percodan, Tylox, others)[8]	q3–4h	available	mg q3–4h; $0.31/5 mg	available	mg/kg q3–4h	available	ar to morphine.	ination with acetaminophen and aspirin limits dosage titration.

[1] Published tables vary in the suggested doses that are equianalgesic to morphine. Clinical response is the criterion that must be applied for each patient; titration to clinical efficacy is necessary. Because there is not complete cross-tolerance among these drugs, it is usually necessary to use a lower than equianalgesic dose initially when changing drugs and to retitrate to response.

[2] Conversion is conservative; therefore, do not use these equianalgesic doses for converting back from fentanyl patch to other opioids because they may lead to inadvertent overdose. Patients may require breakthrough

doses of short-acting opioids during conversion to transdermal fentanyl.

[3] ***Caution:*** For morphine, hydromorphone, and oxymorphone, rectal administration is an alternative route for patients unable to take oral medications. Equianalgesic doses may differ from oral and parenteral doses. A short-acting opioid should normally be used for initial therapy.

[4] Not recommended for chronic pain. Doses listed are for brief therapy of acute pain only. Switch to another opioid for long-term therapy.

[5] ***Caution:*** Recommended doses do not apply for adult patients with kidney or hepatic insufficiency or other conditions affecting drug metabolism.

[6] ***Caution:*** Doses of aspirin and acetaminophen in combination products must also be adjusted to the patient's body weight.

[7] ***Caution:*** Doses of codeine above 60 mg often are not appropriate because of diminishing incremental analgesia with increasing doses but continually increasing nausea, constipation, and other side effects.

[8] ***Caution:*** Monitor total acetaminophen dose carefully, including any OTC use. Total acetaminophen dose maximum 4 g/d. If liver impairment or heavy alcohol use,

maximum is 2 g/d.

Note: Average wholesale price (AWP, generic when available) for quantity listed. Source: *Red Book* Update, Vol. 28, No. 3, March 2009. AWP may not accurately represent the actual pharmacy cost because wide contractual variations exist among institutions.

Adapted from Jacox AK et al. *Management of Cancer Pain: Quick Reference Guide for Clinicians No. 9.* AHCPR Publication No. 94–0593. Rockville, MD. Agency for Health Care Policy and Research, Public Health Service, U.S. Department of Health and Human Services. March 1994.

Reproduced in part, with permission, from Hosp Formul 1994;29(8 Part 2):586. (Erstad BL. A rational approach to the management of acute pain states.) Advanstar Communications, Inc.

Transdermal fentanyl is appropriate for patients already tolerant to other opioids at a dose equivalent to at least 60 mg/d of oral morphine (equivalent to transdermal fentanyl 25 mcg/h every 72 hours) but should not be the first opioid used. Medications that inhibit cytochrome P450 3A4, such as ritonavir, ketoconazole, itraconazole, troleandomycin, clarithromycin, nelfinavir, nefazodone, amiodarone, amprenavir, aprepitant, diltiazem, erythromycin, fluconazole, fosamprenavir, and verapamil, and grapefruit juice can cause increased levels and duration of transdermal fentanyl. Since the fentanyl patch can require 24–48 hours to achieve pharmacologic "steady state," patients should be given short-acting opioids while awaiting the full analgesic effect of transdermal fentanyl.

Meperidine is not useful for chronic pain because it has a short half-life and a toxic metabolite, normeperidine, which can cause irritability and seizures. Partial agonists such as buprenorphine are limited by a dose-related ceiling effect. Mixed agonist-antagonists such as pentazocine and butorphanol tartrate also have a ceiling effect and are contraindicated in patients already receiving full agonist opioids since they may reverse the pain control achieved by the full agonist and cause a withdrawal effect.

A useful technique for opioid management of chronic pain is equianalgesic dosing (Table 5–4). The dosages of any full opioid agonists used to control pain can be converted into an equivalent dose of any other opioid. In this way, 24-hour opioid requirements and dosing regimens established using shorter-acting opioid medications can be converted into equivalent dosages of long-acting medications or formulations. Cross-tolerance is often incomplete, however, so less than the full calculated equianalgesic dosage is generally administered initially when switching between opioid formulations. Equianalgesic dosing for methadone is more complex and varies by dose and duration of use.

While some clinicians and patients inexperienced with the management of severe chronic pain may feel more comfortable with combined nonopioid-opioid agents, full agonist opioids are typically a better choice in patients with severe pain because the dose of opioid is not limited by the toxicities of the acetaminophen, aspirin, or NSAID component of combination preparations. There is no maximal allowable or effective dose for full opioid agonists. The dose should be increased to whatever is necessary to relieve pain, remembering that certain types of pain, such as neuropathic pain, may respond better to agents other than opioids, or to combinations of opioids with these other agents (see below).

While physiologic tolerance is possible with opioids, failure of a previously effective opioid dose to adequately relieve pain is usually due to worsening of the underlying condition causing pain, such as growth of a tumor or a new metastasis in a patient with cancer. In this case, for moderate unrelieved pain, the dose of opioid can be increased by 25–50%. For severe unrelieved pain, a dose increase of 50–100% may be appropriate. The frequency of dosing should be adjusted so that pain control is continuous. Long-term dosing may then be adjusted by adding the amount of short-acting opioid necessary for breakthrough pain over the preceding 24-48 hours to the long-acting medication dose. In establishing or reestablishing adequate dosing, frequent reassessment of the patient's pain and medication side effects is necessary.

As opioids are titrated upwards, increasing difficulty with the side effects can be expected. Constipation is common at any dose of opioid and should be anticipated and prevented in all patients. The prophylaxis and management of opioid-induced constipation are outlined below.

Sedation can be expected with opioids, although tolerance to this effect typically develops within 24–72 hours at a stable dose. Sedation typically appears well before significant respiratory depression. If treatment for sedation is desired, dextroamphetamine (2.5–7.5 mg orally at 8 am and noon) or methylphenidate (2.5–10 mg orally at 8 am and noon) may be helpful. Caffeinated beverages can also help manage minor opioid sedation.

Although sedation is more common, patients may experience euphoria when first taking opioids or when the dose is increased. However, tolerance to this effect typically develops after a few days at a stable dose. At very high doses of opioids, multifocal myoclonus may develop. This symptom may resolve after lowering the dose or switching opioids. While waiting for the level of the offending medication to fall, low doses of lorazepam or dantrolene may be helpful for treating myoclonus.

Nausea due to opioids may occur with initiation of therapy and resolve after a few days. If it is severe or persistent, it can be treated with prochlorperazine, 10 mg orally or intravenously every 8 hours or 25 mg rectally every 6 hours. The most common cause of nausea in patients taking opioids, however, is unrelieved constipation.

Although clinicians may worry about respiratory depression with opioids, that side effect is uncommon when a low dose is given initially and titrated upward slowly. Patients at particular risk for respiratory depression include those with chronic obstructive pulmonary disease and baseline CO_2 retention, those with liver or kidney or combined liver-kidney failure, and those with adrenal insufficiency or frank myxedema. Yet, even patients with severe pulmonary disease can tolerate low-dose opioids, but they should be monitored carefully. Clinicians should not allow concerns about respiratory depression to prevent them from treating pain adequately.

True allergy (with urticaria) to opioids is rare. More commonly, patients will describe intolerance due to side effects such as nausea, pruritus, or urinary retention in response to a particular opioid. If such symptoms develop, they can usually be relieved by lowering the dose or switching to another opioid.

Medications for Neuropathic Pain

It is essential when taking a patient's history to listen for descriptions such as burning, shooting, pins and needles, or electricity, and for pain associated with numbness. Such a history suggests neuropathic pain, which is treated with some medications not typically used for other types of pain. While opioids are effective for neuropathic pain, a number of nonopioid medications have been found to be effective in randomized trials (Table 5–5). The tricyclic antidepressants (TCAs) may provide the greatest relative efficacy and are a good first-line therapy. They usually have an effect within days at lower doses than are needed for an antidepressant effect. Desipramine, 10–200 mg/d orally, and nortriptyline, 10–150 mg/d orally, are good first choices because they cause less orthostatic hypotension and have fewer anticholinergic effects than amitriptyline. Start with a low dosage (10 mg orally daily) and titrate upward every 4 or 5 days.

Table 5–5. Pharmacologic management of neuropathic pain.

Drug[1]	**Starting Dose**	**Typical Dose**
Antidepressants[2]		

Amitriptyline[3]	10 mg orally at bedtime	10–150 mg orally at bedtime
Nortriptyline	10 mg orally at bedtime	10–150 mg orally at bedtime
Desipramine	10 mg orally at bedtime	10–200 mg orally at bedtime
Calcium channel 2- ligands		
Gabapentin[4]	100–300 mg orally once to three times daily	300–1200 mg orally three times daily
Pregabalin[5]	50 mg orally three times daily	100 mg orally three times daily
Selective serotonin norepinephrine reuptake inhibitors		
Duloxetine	60 mg orally daily or 20 mg orally twice daily in elders	60 mg orally daily
Venlafaxine[6]	75 mg orally daily divided into two or three doses	150–225 mg orally daily divided into two or three doses
Opioids	(see Table 5–4)	(see Table 5–4)
Other medications		
Lidocaine	5% patch applied	1–3 patches

transdermal	daily, for a maximum of 12 hours	applied daily for a maximum of 12 hours
Tramadol hydrochloride	50 mg orally four times daily	100 mg orally two to four times daily

[1] Begin at the starting dose and titrate up every 4 or 5 days.

[2] Begin with a low dose. Pain relief may be achieved at doses below antidepressant doses, thereby minimizing adverse side effects.

[3] Avoid in elders because it has more severe anticholinergic effects.

[4] Common side effects include nausea, somnolence, and dizziness. Take medication on a full stomach. Do not combine with serotonin or norepinephrine uptake inhibitors, or with tricyclic antidepressants.

[5] Common side effects include dizziness, somnolence, peripheral edema, and weight gain. Must adjust dose for kidney impairment.

[6] Caution: Can cause hypertension and ECG changes. Obtain baseline ECG and monitor.

The calcium channel 2- ligands gabapentin and pregabalin are also considered first-line therapy for neuropathic pain. Both medications can cause sedation, dizziness, ataxia, and gastrointestinal side effects but have no significant drug interactions. Both drugs require dose adjustments in patients with kidney dysfunction. Gabapentin should be started at low dosages of 100–300 mg orally three times a day and titrated upward by 300 mg/d every 4 or 5 days with a typical effective dose of 1800–3600 mg/d. Pregabalin should be started at 150 mg/d in two or three divided doses. If necessary, the dose of pregabalin can be titrated upward to 300–600 mg/d in two or three divided doses. Both drugs are relatively safe in accidental overdosage and may be preferred over TCAs for a patient with a history of congestive heart failure or arrhythmia or if there is a risk of suicide. Gabapentin plus morphine in combination is more effective at lower doses of each drug than when each is used as a single agent.

The selective serotonin norepinephrine reuptake inhibitors (SSNRIs), duloxetine (60 mg/d or 20 mg twice daily in elders), and venlafaxine (150–225 mg/d) are also considered first-line treatments for neuropathic pain. Patients should be advised to take duloxetine on a full stomach because nausea is a common side effect. Duloxetine should not be combined with other serotonin or norepinephrine uptake inhibitors, but it can be combined with gabapentin or pregabalin. Because venlafaxine can cause hypertension and induce ECG changes, patients with cardiovascular risk factors should be carefully monitored when starting this drug.

Opioids and tramadol are also effective for neuropathic pain. Tramadol should be started at 50 mg orally daily and can be titrated up to 100 mg orally four times daily.

The 5% lidocaine patch (1–34 patches at a time) is effective in postherpetic neuralgia and may be effective in other types of localized neuropathic pain. A new patch is applied to the painful region daily for up to 12 hours.

Successful management of neuropathic pain often requires the use of more than one effective medication.

Adjuvant Pain Medications & Treatments

If pain cannot be controlled without uncomfortable medication side effects, clinicians should consider using lower doses of multiple medications, as is done commonly for neuropathic pain, rather than larger doses of one or two medications. For bone pain, the anti-inflammatory effect of NSAIDs can be particularly helpful. Radiation therapy and bisphosphonates may also relieve bone pain. For some patients, a nerve block can provide substantial relief, such as a celiac plexus block for pain from pancreatic cancer. Intrathecal pumps may be useful for patients with severe pain responsive to opioids but who require such large doses that systemic side effects (eg, sedation and constipation) become limiting.

There is some evidence for the use of cannabinoids as analgesics. Chemotherapeutic agents can be used for symptom management with palliative intent.

Corticosteroids such as dexamethasone or prednisone can be helpful for patients with headache due to increased intracranial pressure, pain from spinal cord compression, metastatic bone pain, and neuropathic pain due to invasion or infiltration of nerves by tumor. Because of the side effects of long-term corticosteroid administration, they are most appropriate in patients with end-stage disease. Low-dose intravenous or oral ketamine has been used successfully for neuropathic and other pain syndromes poorly responsive to opioids. Haloperidol and benzodiazepines may be used prophylactically to minimize ketamine's psychotomimetic side effects.

Nonpharmacologic Treatments

Nonpharmacologic therapies are also valuable in treating pain. Hot or cold packs, massage, and physical therapy can be helpful for musculoskeletal pain. Similarly, biofeedback, acupuncture, chiropractic, meditation, music therapy, cognitive behavioral therapy, guided imagery, cognitive distraction, and framing may be of help in treating pain. Because mood and psychological issues play an important role in the patient's perception of and response to pain, psychotherapy, support groups, prayer, and pastoral counseling can also help in the management of pain. Major depression, which may be instigated by chronic pain or may alter the response to pain, should be treated aggressively.

When to Refer

- Pain not responding to opioids at typical doses.
- Neuropathic pain not responding to first-line treatments.
- Complex methadone management issues.
- Intolerable side effects from oral opioids.
- Severe pain from bone metastases.
- For a surgical or anesthesia-based procedure, intrathecal pump, or nerve block.

When to Admit

- Patients should be hospitalized for severe exacerbation of pain that is not responsive to previous stable oral opioid around-the-clock plus breakthrough doses.
- Patients whose pain is so severe that they cannot be cared for at home should be hospitalized.
- Uncontrollable side effects from opioids, including nausea, vomiting, and altered mental status, should prompt hospitalization.

Dyspnea

Dyspnea is the subjective experience of difficulty breathing and may be characterized by patients as tightness in the chest, shortness of breath, or a feeling of suffocation. Up to 50% of terminally ill patients may experience severe dyspnea.

Treatment of dyspnea is usually first directed at the cause (see Chapter 9: Pulmonary Disorders). At the end of life, dyspnea is often treated nonspecifically with opioids. Immediate-release morphine orally or intravenously treats dyspnea effectively and typically at doses lower than would be necessary for the relief of moderate pain. Supplemental oxygen may be useful for the dyspneic patient who is hypoxic and may provide subjective benefit to other dyspneic patients as well. However, a nasal cannula and face mask are sometimes not well tolerated, and fresh air from a window or fan may provide relief. Judicious use of nonpharmacologic relaxation techniques such as meditation and guided imagery may be beneficial for some patients. Benzodiazepines may be useful for the anxiety associated with dyspnea but do not appear to act directly to relieve dyspnea.

Nausea & Vomiting

Nausea and vomiting are common and distressing symptoms. As with pain, the management of nausea may be maximized by regular dosing. An understanding of the four major inputs to the vomiting center may help direct treatment (see Chapter 15: Gastrointestinal Disorders).

Vomiting associated with a particular opioid may be relieved by substitution with an equianalgesic dose of another opioid or a sustained-release formulation. In addition to the other dopamine receptor antagonist antiemetics listed in Table 15–2 that block the trigger zone, haloperidol (0.5–2 mg orally every 4–6 hours) is commonly used.

Vomiting may be due to stimulation of peripheral afferent nerves from the gut. Offering patients small amounts of food only when they are hungry may prevent nausea and vomiting. Nasogastric suction may provide rapid, short-term relief for vomiting associated with constipation, gastroparesis, or gastric outlet obstruction, with the addition of laxatives, prokinetic agents (only in the setting of partial not complete obstruction) such as metoclopramide (10–20 mg orally or intravenously four times a day), scopolamine (1.5-mg patch every 3 days), and high-dose corticosteroids as more definitive treatment. Nausea often requires treatment with more than one agent; when it is refractory to other treatments or due to increased intracranial pressure, it may respond to high-dose corticosteroids (eg, dexamethasone, 20 mg orally or intravenously daily in divided doses).

Vomiting due to disturbance of the vestibular apparatus may be treated with anticholinergic and antihistaminic agents (including diphenhydramine, 25 mg orally or intravenously every 8 hours, or scopolamine, 1.5-mg patch every 3 days).

Benzodiazepines can be effective in preventing the anticipatory nausea associated with chemotherapy but are otherwise not indicated for nausea and vomiting. Finally, many patients find medical marijuana or dronabinol (2.5–20 mg orally every 4–6 hours) helpful in the management of nausea and vomiting.

Constipation

Given the frequent use of opioids, poor dietary intake, and physical inactivity, constipation is a common problem among the dying. Clinicians must inquire about any difficulty with hard or infrequent stools. Constipation is an easily preventable and treatable cause of discomfort, distress, and nausea and vomiting (see Chapter 15: Gastrointestinal Disorders).

Constipation may be prevented or relieved if patients can increase their activity and their intake of dietary fiber and fluids. Simple considerations such as privacy, undisturbed toilet time, and a bedside commode rather than a bedpan may be important for some patients.

For patients taking opioids, anticipating and preventing constipation is important. A prophylactic bowel regimen of stool softeners (docusate) and stimulants (bisacodyl or senna) should be started when opioid treatment is begun. Table 15–4 lists other agents that can be added as needed. Methylnaltrexone, a new subcutaneous medication, is a peripherally acting mu-receptor antagonist and holds promise for severe, unrelieved, opioid-induced constipation.

Delirium & Agitation

Many terminally ill patients die in a state of delirium—a disturbance of consciousness and a change in cognition that develops over a short time and is manifested by misinterpretations, illusions, hallucinations, disturbances in the sleep-wake cycle, psychomotor disturbances (eg, lethargy, restlessness), and mood disturbance (eg, fear, anxiety). Delirium complicated by myoclonus or convulsions at the end of life has been called **terminal restlessness.**

Careful attention to patient safety and nonpharmacologic strategies to help the patient remain oriented (clocks, calendars, a familiar environment, reassurance and redirection from caregivers) may be sufficient to prevent or manage minor delirium. Some delirious patients may be "pleasantly confused," and a decision by the patient's family and the clinician not to treat delirium may be justified.

More commonly, however, delirium at the end of life is distressing to patients and family and requires treatment. Delirium may interfere with the family's ability to feel comforting to the patient and may prevent a patient from being able to recognize and report important symptoms.

While there are many reversible causes of delirium (see Chapter 25: Psychiatric Disorders), identifying and correcting the underlying cause at the end of life is often simply a question of attention to the choice and dosing of psychoactive medications.

When the cause of delirium cannot be identified, treated, or corrected rapidly enough, delirium may be treated symptomatically with neuroleptics, such as haloperidol (1–10 mg orally, subcutaneously, intramuscularly, or intravenously twice or three times a day) or risperidone (1–3 mg orally twice a day). The benefits of neuroleptics in the treatment of agitation must be weighed carefully against potential harms, based on mounting data showing an association between antipsychotic medications and increased mortality for older adults with dementia. When delirium is refractory to treatment and remains intolerable, sedation may be required to provide relief and may be achieved rapidly with midazolam (0.5–5 mg/h subcutaneously or intravenously) or barbiturates.

The End of Life

Definition of the End of Life

In the United States, approximately 2.5 million people die each year. Caring for patients at the end of life is an important responsibility and a rewarding opportunity for clinicians. Clinicians battling to prolong life must recognize when life is ending in order to continue caring properly for their patients. Unfortunately, most clinical practice guidelines do not include significant attention to end-of-life care. End-of-life care refers to focusing care for those approaching death on the goals of relieving distressing symptoms and promoting quality of life rather than attempting to cure underlying disease. From the medical perspective, the end of life may be defined as that time when death—whether due to terminal illness or acute or chronic illness—is expected within weeks to months and can no longer be reasonably forestalled by medical intervention.

Prognosis at the End of Life

Clinicians must help patients understand when they are approaching the end of life. This information influences patients' treatment decisions and may change how they spend their remaining time. While certain diseases such as cancer are more amenable to prognostic estimates regarding the time course to death, the other common causes of mortality in the United States—including heart disease, stroke, chronic lung disease, and dementia—have more variable trajectories and difficult to predict prognoses (Figure 5–1). Even for patients with cancer, clinician estimates of prognosis are often inaccurate and generally overly optimistic. Nonetheless, clinical experience, epidemiologic data, guidelines from professional organizations (eg, the National Hospice Organization), and computer modeling and prediction tools (eg, the Acute Physiology and Chronic Health Evaluation [APACHE] system, the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment [SUPPORT] model, or the Palliative Performance Scale) may be used to help patients identify the end period of their lives. Clinicians can also ask themselves "Would I be surprised if this patient died in the next year?" to determine whether a discussion of prognosis and focus on end-of-life care would be appropriate. If the answer is "no," then the clinician should initiate a discussion. Recognizing that patients may have different levels of comfort with prognostic information, clinicians can introduce the topic by simply saying, "I have information about the likely time course of your illness. Would you like to talk about it?"

Expectations about the End of Life

Patients' experiences at the end of life are influenced by their expectations about how they will die and the meaning of death. Many people fear how they will die more than death itself. Patients report fears of dying in pain or of suffocation, of loss of control, indignity, isolation, and of being a burden to their families. All of these anxieties may be ameliorated with good supportive care provided by an attentive group of caretakers.

Death is often regarded by clinicians, patients, and families as a failure of medical science. This attitude can create or heighten a sense of guilt about the failure to prevent dying. Both the general public and clinicians often are complicit in denying death, treating dying persons merely as patients and death as an enemy to be battled furiously in hospitals rather than as an inevitable outcome to be experienced as a part of life at home. As a result, approximately 75–80% of people in the United States die in hospitals or long-term care facilities.

Even when the clinician continues to pursue cure of potentially reversible disease, offering comfort and helping the patient prepare for death are foremost considerations. Patients at the end of life and their families identify a number of elements as important to quality end-of-life care: managing pain and other symptoms adequately, avoiding inappropriate prolongation of dying, preserving dignity, preparing for death, achieving a sense of control, relieving the burden on others, and strengthening relationships with loved ones.

Communication & Care of the Patient

Caring for patients at the end of life requires the same skills clinicians use in other tasks of medical care: diagnosing treatable conditions, providing patient education, facilitating decision-making, and expressing understanding and caring. Communication skills are vitally important. Higher-quality communication is associated with greater satisfaction and awareness of patient wishes. When needed, the use of a professional interpreter can facilitate clear communication and help broker cultural issues. In particular, clinicians must become proficient at delivering bad news and then dealing with its consequences (Table 5–6).

Table 5–6. Suggestions for the delivery of bad news.
Prepare an appropriate place and time.
Address basic information needs.
Be direct; avoid jargon and euphemisms.
Allow for silence and emotional ventilation.
Assess and validate patient reactions.
Respond to immediate discomforts and risks.
Listen actively and express empathy.
Achieve a common perception of the problem.
Reassure about pain relief.
Ensure basic follow-up and make specific plans for the future.

Three further obligations are central to the clinician's role at this time. First, he or she must work to identify, understand, and relieve suffering, which may include physical, psychological, social, or spiritual distress. In assisting with redirection and growth, providing support, assessing meaning, and fostering transcendence, clinicians can help ameliorate their patients' suffering and help the patient live fully during this stage of life.

Second, clinicians can serve as facilitators or catalysts for hope. While a particular outcome may be extremely unlikely (such as cure of advanced cancer following exhaustive conventional and experimental treatments), hope may be defined as the patient's belief in what is *still* possible. Although expecting a "miraculous cure" may be simplistic and even harmful, hope for relief of pain, for reconciliation with loved ones, for discovery of meaning, and for spiritual transformation is realistic at the end of life. With such questions as "What is still possible now for you?" "When you look to the future, what do you hope for?" "What good might come of this?" clinicians can help patients uncover hope, explore meaningful and realistic goals, and develop strategies to realize them.

Third, dying patients' feelings of isolation and fear demand that clinicians assert that care will continue to be provided throughout the final stage of life. The promise of nonabandonment is perhaps the central principle of end-of-life care and is a clinician's pledge to an individual patient to serve as a caring partner, a resource for creative problem-solving and relief of suffering, a guide during uncertain times, and a witness to the patient's experiences—no matter what happens. Clinicians can say to a patient, "I will care for you whatever happens." Dying patients need their clinicians to offer their presence—not necessarily the ability to solve all problems but rather a commitment to recognize and receive the patients' difficulties and experiences with respect and empathy. At its best, the patient-clinician relationship can be a covenant of compassion and a recognition of common humanity.

Caring for the Family

In caring for patients at the end of life, clinicians must appreciate the central role played by family, friends, and romantic partners and often must deal with strong emotions of fear, anger, shame, sadness, and guilt experienced by those individuals. While significant others may support and comfort a patient at the end of life, the threatened loss of a loved one may also create or reveal dysfunctional or painful family dynamics. Furthermore, clinicians must be attuned to the potential impact of illness on the patient's family: substantial physical caregiving responsibilities and financial burdens as well as increased rates of anxiety, depression, chronic illness, and even mortality. Family caregivers, typically women, commonly provide the bulk of care for patients at the end of life, yet their work is often not acknowledged or compensated.

Clinicians can help families confront the imminent loss of a loved one (Table 5–7) and often must negotiate amid complex and changing family needs. Identifying a spokesperson for the family, conducting family meetings, allowing all to be heard, and providing time for consensus may help the clinician work effectively with the family.

Table 5–7. Clinician interventions helpful to families of dying patients.
Excellent communication, including physician willingness to talk about death, timely and clear information, proactive guidance, listening, and empathic responses
Advance care planning and clear decision-making, including culturally sensitive communication, achieving consensus among family members and an understanding that surrogate decision-makers are trying to determine what the *patient* would have wanted, not what the surrogate would want
Support for home care, including orienting family members to the scope and details of family caregiving, providing clear direction about how to contact professional caregivers, and informing patients and families of the benefits of hospice care
Empathy for family emotions and relationships, including recognizing and validating common positive and negative feelings
Attention to grief and bereavement, including support for anticipatory grief and follow up with the family after the patient's death

Adapted, with permission, from Rabow MW et al. Supporting family caregivers at the end of life: "they don't know what they don't know." JAMA. 2004 Jan 28;291(4):483–91.

Clinician Self-care

Many clinicians find caring for patients at the end of life to be one of the most rewarding aspects of practice. However, working with the dying requires tolerance of uncertainty, ambiguity, and existential challenges. Clinicians must recognize and respect their own limitations and attend to their own needs in order to avoid being overburdened, overly distressed, or emotionally depleted. Open recognition of their own feelings enables clinicians to process their emotions and take steps to care for themselves: conferring and consulting with colleagues, retreating, relaxing and recuperating, obtaining informal or professional support, or even—under extraordinary circumstances—transferring the care of a patient to another clinician when it is no longer possible for the original clinician to meet the patient's needs. Moreover, care of patients at the end of life is not solely the responsibility of physicians. Physicians, nurses, social workers, chaplains, pharmacists, and other clinicians should coordinate their efforts as part of an interdisciplinary team to care for patients and support one another.

The Setting & Structure of Care

Ethical & Legal Background

Clinicians may feel a sense of moral obligation to provide potentially life-prolonging interventions to patients who are dying. While the ethical, legal, and professional controversies over "aid in dying" are beyond the scope of this chapter, clinicians should be aware of the "right to die" movement as an expression, at least in part, of patient dissatisfaction with how people are cared for at the end of life. In the United States, "aid in dying" (inaccurately but commonly referred to as "assisted suicide") is illegal in every state but Oregon and Washington—and legal there only with careful restrictions. Research has demonstrated that palliative care interventions can cause some patients who have requested "aid in dying" to withdraw their request. While individual clinicians must decide for themselves what their personal limits may be in caring for patients who request "aid in dying," all clinicians can reclaim their long-privileged and universally accepted role of caring for the dying.

Clinicians' care of patients at the end of life is guided by the same ethical and legal principles that inform other types of medical care. Foremost are truth-telling, nonmaleficence, beneficence, autonomy, confidentiality, proportionality, and distributive justice. Important ethical principles may come into conflict when caring for patients. For example, while a patient may desire a particular medical intervention, the clinician may decline to undertake the intervention if it is of no therapeutic benefit (ie, futile) or violates the clinician's own moral code. Clinicians must use caution in invoking futility, since what constitutes futility is often a matter of controversy. Studies confirm that most disagreements can be resolved through repeated discussions between clinicians and families. Although clinicians and family members often feel differently about withholding versus withdrawing support, there is consensus among ethicists, supported by legal precedent, of their ethical equivalence. Patients and their surrogates have the same right to stop unwanted medical treatments once begun as they do to refuse those treatments in the first place, including nutrition and hydration. The ethical principle of "double effect" argues that the potential to hasten imminent death is acceptable if it comes as the known but unintended consequence of a primary intention to provide comfort and relieve suffering. For example, sufficient doses of morphine should be provided to control pain even if there is the known unintended effect of depressing respiration.

Decision-making, Advance Care Planning, & Advance Directives

Well-informed, competent adults have a right to refuse medical intervention even if this is likely to result in death. Many are willing to sacrifice some quantity of life to protect a certain quality of life. In order to promote patient autonomy, clinicians are obligated to inform patients about the risks, benefits, alternatives, and expected outcomes of end-of-life medical interventions such as cardiopulmonary resuscitation (CPR), mechanical ventilation, vasopressor medication, hospitalization and ICU care, and nutrition and hydration. Advance directives are oral or written statements made by patients when they are competent that are intended to guide care should they become incompetent. Advance directives allow patients to project their autonomy into the future and are an important part of advance care planning—a process whereby patients consider various paths their illness may take and contingencies for responding to these possible developments based on their care goals and values. Advance directives take effect when the patient can no longer communicate his or her preferences directly. While oral statements about these matters are ethically binding, they are not legally binding in all states. State-specific advance directive forms are available from a number of sources, including http://www.caringinfo.org.

In addition to documenting patient preferences for care, the Durable Power of Attorney for Health Care (DPOA-HC) allows the patient to designate a surrogate decision-maker. The DPOA-HC is important since it is often difficult to anticipate what decisions will need to be made. The responsibility of the surrogate is to provide "substituted judgment"—to decide as the *patient* would, not as the *surrogate* wants. Clinicians should encourage patients to talk with their surrogates about their preferences generally and about scenarios that are likely to arise, such as the need for mechanical ventilation in a patient with end-stage emphysema. In the absence of a designated surrogate, clinicians usually turn to family members or next of kin. Clinicians should educate all patients—ideally, well before the end of life—about the opportunity to formulate an advance directive. Most patients with serious illness have already thought about end-of-life issues, want to discuss them with their clinician, want the clinician to bring up the subject, and feel better for having had the discussion. Despite regulations requiring health care institutions to inform patients of their rights to formulate an advance directive, only about 10% of people in the United States (including clinicians themselves) actually have completed them.

Do Not Attempt Resuscitation Orders

As part of advance care planning, clinicians can encourage patients to express their preferences about the use of CPR. Most patients and many clinicians are uninformed or misinformed about the nature and success of CPR. Only about 15% of all patients who undergo CPR in the hospital survive to hospital discharge. Moreover, among certain populations—especially those with serious systemic noncardiac disease, metastatic cancer, and sepsis—the likelihood of survival to hospital discharge following CPR is virtually nil.

Patients may ask their clinician to write an order that CPR not be attempted on them. Although this order initially was referred to as a DNR (do not resuscitate) order, many clinicians prefer the term "DNAR" (do not attempt resuscitation) to emphasize the low likelihood of success.

Patients deciding about CPR preferences should also be informed about the sequelae of surviving CPR. These may include fractured ribs, lacerated internal organs, and neurologic disability, and the frequent need for other aggressive interventions, such as ICU care, if CPR is successful.

For some patients at the end of life, decisions about CPR may not be about whether they will live but about how they will die. Clinicians should correct the misconception that withholding CPR in appropriate circumstances is tantamount to "not doing everything" or "just letting someone die." While respecting the patient's right ultimately to make the decision—and keeping in mind their own biases and prejudices—clinicians should offer explicit recommendations about DNAR orders and protect dying patients and their families from feelings of guilt and from the sorrow associated with vain hopes. Clinicians should encourage patients and their families to make proactive decisions about what is wanted in end-of-life care rather than focusing only on what is not to be done. For patients with pacemakers and internal cardiac defibrillators, clinicians must also address issues of turning off these devices as death approaches to prevent them from discharging during the dying process.

Hospice & Other Palliative Care Institutions

Hospice is an approach to end-of-life care where the most urgent objective is to address the physical and emotional needs of the dying. In the United States, 39% of people who die use hospice. While some hospice care is provided in hospitals and institutional residences, about 80% of patients receiving hospice care remain at home where they can be cared for by their family and visiting hospice staff. Hospice care focuses on the patient and family rather than the disease and on providing comfort and pain relief rather than on treating illness or prolonging life. Hospices provide intensive caring with the goal of helping people live well until they die.

Hospice embodies the palliative care philosophy that emphasizes individualized attention, human contact, and an interdisciplinary team approach. Hospice care can include arranging for respite for family caregivers and providing legal, financial, and other services. Primary care clinicians are strongly encouraged to continue caring for their patients during the time they are receiving hospice care.

Hospice care is highly rated by families and has been shown to increase patient satisfaction, to reduce costs (depending on when patients are referred to hospice care), and even to decrease family caregiver mortality. Hospice care tends to be used late in the course of the end of life. The average length of stay in hospices in the United States is 67 days, with 31% of patients dying within 7 days after beginning hospice care.

Most hospice organizations require clinicians to estimate the patient's probability of survival to be less than 6 months, since this is a criterion for eligibility to receive Medicare or other insurance coverage. Regrettably, the hospice benefit can be difficult to provide to people who are homeless or isolated or who have terminal prognoses that are difficult to quantify.

While the initiation of hospice care is often described as a transition from aggressive care to comfort care, hospice care also provides "aggressive" care, though not directed at achieving a cure or prolonging life. It is more appropriate to consider hospice care as one among many health care resources available to patients at the end of life. Helping patients decide when to avail themselves of the resources of hospice care is an important function even for clinicians providing the most aggressive and intensive curative medical interventions. One advantage of providing palliative care *simultaneously* with other medical treatment early on is that it avoids any decision about when to start palliative care and negative connotations for the patient. While most people prefer to die at home, inpatient palliative care may be more appropriate for patients with complex, severe symptoms that are difficult to manage at home.

Cultural Issues

The individual patient's experience of dying occurs in the context of a complex interaction of personal, philosophic, and cultural influences. Various religious, ethnic, gender, class, and cultural traditions help determine patients' styles of communication, comfort in discussing particular topics, expectations about dying and medical interventions, and attitudes about the appropriate disposition of dead bodies. There are differences in knowledge and beliefs regarding advance directives, autopsy, organ donation, hospice care, and withdrawal of life-sustaining interventions among patients of different ethnic groups. Clinicians must appreciate recent evidence suggesting that palliative care is susceptible to some of the same racial biases previously documented in other medical disciplines. While each patient is an individual, being sensitive to a person's cultural beliefs and respecting ethnic traditions are important responsibilities of the clinician caring for a patient at the end of life, especially when the cultures of origin of the clinician and patient differ. A clinician may ask a patient, "What do I need to know about you and your beliefs that will help me take care of you?"

Nutrition & Hydration

Individuals at the end of life have a right to refuse nutrition and hydration. However, providing or withholding oral food and water is not simply a medical decision because feeding may have profound social and cultural significance for patients, families, and clinicians themselves. Withholding supplemental enteral or parenteral nutrition and hydration challenges the assumption that offering food is an expression of compassion and love and invokes distressing images of starvation. In fact, individuals at the end of life who choose to forgo nutrition and hydration are unlikely to suffer from hunger or thirst. Family and friends can be encouraged to express their love and caring in ways other than intrusive attempts at force feeding or hydration.

Tube feedings do not prevent aspiration pneumonia, and there is debate about whether artificial nutrition prolongs life in the terminally ill. In fact, there has been a growing awareness of the potential medical benefits of forgoing unwanted or artificial nutrition and hydration (including tube feedings, parenteral nutrition, and intravenous hydration) at the end of life.

Eating when not hungry and artificial nutrition are associated with a number of potential complications. Force feeding may cause nausea and vomiting in ill patients, and eating will lead to diarrhea in the setting of malabsorption. Nutrition may increase oral and airway secretions and the risk of choking, aspiration, and dyspnea. Nasogastric and gastrostomy tube feeding and parenteral nutrition impose risks of infection, epistaxis, pneumothorax, electrolyte imbalance, and aspiration—as well as the need to physically restrain the delirious patient to prevent dislodgment of catheters and tubes.

Withholding nutrition at the end of life causes remarkably little hunger or distress. Ill people often have no hunger with total caloric deprivation, and the associated ketonemia produces a sense of well-being, analgesia, and mild euphoria. However, carbohydrate intake even in small amounts (such as that provided by 5% intravenous dextrose solution) blocks ketone production and may blunt the positive effects of total caloric deprivation.

Withholding hydration may lead to death in a few days to a month. The quality of life for those at the end of life may be adversely affected by supplemental hydration because of its contribution to oral and airway secretions (leading to aspiration or the "death rattle"), polyuria, and the development or worsening of ascites, pleural or other effusions, and peripheral and pulmonary edema.

Although it is unclear to what extent withholding hydration at the end of life creates an uncomfortable sensation of thirst, any such sensation is usually relieved by simply moistening the dry mouth. Ice chips, hard candy, swabs, and minted mouthwash or a solution of equal parts nystatin solution, viscous lidocaine, and diphenhydramine for pain or discomfort associated with dry mouth are effective.

Withdrawal of Curative Efforts

Requests from appropriately informed and competent patients or their surrogates for withdrawal of life-sustaining interventions must be respected. In addition, clinicians may determine unilaterally that particular interventions are medically inappropriate—eg, continuing kidney dialysis in a patient dying of multiorgan failure. In such cases, the clinician's intention to withdraw a specific intervention should be communicated to the patient and family. If differences of opinion exist about the appropriateness of what is being done, the assistance of an institutional ethics committee should be sought.

Limitation of life support prior to death is an increasingly common practice in intensive care units. The withdrawal of life-sustaining interventions such as mechanical ventilation must be approached carefully to avoid needless patient suffering and distress for those in attendance. Clinicians should educate the patient and family about the expected course of events and the difficulty of determining the precise timing of death after withdrawal of interventions. Sedative and analgesic agents should be administered to ensure patient comfort even at the risk of respiratory depression or hypotension. Scopolamine (10 mcg/h subcutaneously or intravenously, or a 1.5-mg patch every 3 days), glycopyrrolate (1 mg orally every 4 hours), or atropine (1% ophthalmic solution, 1 or 2 drops sublingually as often as every hour) can be used for controlling airway secretions and the resultant "death rattle." A guideline for withdrawal of mechanical ventilation is provided in Table 5–8.

Table 5–8. Guidelines for withdrawal of mechanical ventilation.
1. Stop neuromuscular blocking agents.
2. Administer opioids or sedatives to eliminate distress.
If not already sedated, begin with fentanyl 100 mcg (or morphine sulfate 10 mg) by intravenous bolus and infusion of fentanyl 100 mcg/h intravenously (or morphine sulfate 10 mg/h intravenously).
Distress is indicated by RR > 24, nasal flaring, use of accessory muscles of respiration, HR increase > 20%, MAP increase > 20%, grimacing, clutching.
3. Discontinue vasoactive agents and other agents unrelated to patient comfort, such as antibiotics, intravenous fluids, and diagnostic procedures.
4. Decrease FIO_2 to room air and PEEP to 0 cm H_2O.
5. Observe patient for distress.
If patient is distressed, increase opioids by repeating

bolus dose and increasing hourly infusion rate by 50 mcg fentanyl (or 5 mg morphine sulfate),[1] then return to observation.
If patient is not distressed, place on T piece and observe.
If patient continues without distress, extubate patient and continue to observe for distress.

[1] Ventilatory support may be increased until additional opioids have effect.

RR, respiratory rate; HR, heart rate; MAP, mean airway pressure; FIO_2, fraction of inspired oxygen; PEEP, positive end-expiratory pressure.

Psychological, Social, & Spiritual Issues

Dying is not exclusively or even primarily a biomedical event. It is an intimate personal experience with profound psychological, interpersonal, and existential meanings. For many people at the end of life, the prospect of impending death stimulates a deep and urgent assessment of their identity, the quality of their relationships, and the meaning and purpose of their existence.

Psychological Challenges

In 1969, Elisabeth Kübler-Ross identified five psychological stages or patterns of emotions that patients at the end of life may experience: denial and isolation, anger, bargaining, depression, and acceptance. Not every patient will experience all these emotions, and typically not in an orderly progression. In addition to these five stages are the perpetual challenges of anxiety and fear of the unknown. Simple information, listening, assurance, and support may help patients with these psychological challenges. In fact, patients and families rank emotional support as one of the most important aspects of good end-of-life care. Psychotherapy and group support may be beneficial as well.

Despite the significant emotional stress of facing death, clinical depression is not normal at the end of life and should be treated. Cognitive and affective signs of depression (such as hopelessness) may help distinguish depression from the low energy and other vegetative signs common with end-stage illness. Although traditional antidepressant treatments such as selective serotonin reuptake inhibitors are effective, more rapidly acting medications such as dextroamphetamine or methylphenidate (in doses used for sedation described earlier in this chapter) may be particularly useful when the end of life is near or while waiting for other antidepressant medication to take effect.

Social Challenges

At the end of life, patients should be encouraged to discharge personal, professional, and business obligations. This might include completing important work or personal projects, distributing possessions, writing a will, and making funeral and burial arrangements. The prospect of death often prompts patients to examine the quality of their interpersonal relationships and to begin the process of saying goodbye (Table 5–9). Dying may intensify a patient's need to feel cared for by the doctor and the need for clinician empathy and compassion. Concern about estranged relationships or "unfinished business" with significant others and interest in reconciliation may become paramount at this time.

Table 5–9. Five statements often necessary for the completion of important interpersonal relationships.

(1) "Forgive me."	(An expression of regret)
(2) "I forgive you."	(An expression of acceptance)
(3) "Thank you."	(An expression of gratitude)
(4) "I love you."	(An expression of affection)
(5) "Good-bye."	(Leave-taking)

Spiritual Challenges

Spirituality is the attempt to understand or accept the underlying meaning of life, one's relationships to oneself and other people, one's place in the universe, and the possibility of a "higher power" in the universe. Spirituality is distinguished from particular religious practices or beliefs and is generally considered a universal human concern.

Perhaps because of an inappropriately exclusive attention to the biologic challenge of forestalling death or perhaps from feelings of discomfort or incompetence, clinicians frequently ignore their patients' spiritual concerns or reflexively refer these important issues to chaplains, psychiatrists or other caretakers (nurses, social workers, clergy). However, the existential challenges of dying are central to the well-being of people at the end of life and are the proper concern of clinicians. Clinicians can help dying patients by providing care to the whole person—by providing physical comfort and social support and by helping patients discover their own unique meaning in the world and an acceptance of death as a part of life.

Unlike physical ailments such as infections and fractures, which usually require a clinician's intervention to be treated, the patient's spiritual concerns often require only a clinician's attention, listening, and witness. Clinicians might choose to inquire about the patient's spiritual concerns and ask whether the patient wishes to discuss them. For example, asking, "How are you within yourself?" communicates that the clinician is interested in the patient's whole experience and provides an opportunity for the patient to share perceptions about his or her inner life. Questions that might constitute an existential "review of systems" are presented in Table 5–10.

Table 5–10. An existential review of systems.
Intrapersonal
How are you within yourself?
What does your illness/dying mean to you?
What do you think caused your illness?
How have you been healed in the past?
What do you think is needed for you to be healed now?
What is right with you now?
What do you hope for?
Interpersonal
Who is important to you?

To whom does your illness/dying matter?
Do you have any unfinished business with significant others?
Transpersonal
What is your source of strength, help, or hope?
Do you have spiritual concerns or a spiritual practice?
If so, how does your spirituality relate to your illness/dying, and how can I help integrate your spirituality into your health care?
What do you think happens after we die?
What purpose might your illness/dying serve?
What do you think is trying to happen here?

Attending to the spiritual concerns of patients calls for listening to their stories. Story-telling gives patients the opportunity to verbalize what is meaningful to them and to leave something of themselves behind—a legacy, the promise of being remembered. Story-telling may be facilitated by suggesting that the patient share his or her life story with family members, record it on audio or video tape, assemble a photo album, organize a scrapbook, or write an autobiography.

While dying may be a period of inevitable loss of physical functioning, the end of life also offers an opportunity for psychological, interpersonal, and spiritual development.

Individuals may grow—even achieve a heightened sense of well-being or transcendence—in the process of dying. Through listening, support, and presence, clinicians may help foster this learning and be a catalyst for this transformation. Rather than thinking of dying simply as the termination of life, clinicians and patients may be guided by a developmental model of dying that recognizes a series of lifelong developmental tasks and landmarks and allows for growth at the end of life.

Tasks After Death

After the death of a patient, the clinician is called upon to perform a number of tasks, both required and recommended. The clinician must plainly and directly inform the family of the death, complete a death certificate, contact an organ procurement organization, and request an autopsy. Providing words of sympathy and reassurance, time for questions and initial grief, and a quiet private room for the family at this time is appropriate and much appreciated.

The Pronouncement & Death Certificate

In the United States, state policies direct clinicians to confirm the death of a patient in a formal process called "pronouncement." The clinician must verify the absence of spontaneous respirations and cardiac activity. A note describing these findings and the time of death is entered in the patient's chart. In many states, when a patient whose death is expected dies outside of the hospital (at home or in prisons, for example) nurses may be authorized to report the death over the telephone to a physician who must then sign the death certificate within 24 hours. For traumatic deaths, some states allow emergency medical technicians to pronounce a patient dead at the scene based on clearly defined criteria and with physician telephonic or radio supervision.

While the pronouncement may often seem like an awkward and unnecessary formality, clinicians may use this time to reassure the patient's loved ones at the bedside that the patient died peacefully and that all appropriate care had been given. Both clinicians and families may use the ritual of the pronouncement as an opportunity to begin to process emotionally the death of the patient.

Physicians are legally required to accurately report the underlying cause of death on the death certificate. This reporting is important both for patients' families (for insurance purposes and the need for an accurate family medical history) and for the epidemiologic study of disease and public health. Physicians are untrained in and unskilled at correctly completing death certificates. The physician should be specific about the major cause of death being the condition without which the patient would not have died (eg, "decompensated cirrhosis") and its contributory cause (eg, "hepatitis B and hepatitis C infections and chronic alcoholic hepatitis") as well as any associated conditions (eg, "acute kidney failure")—and not simply put down "cardiac arrest" as the cause of death.

Autopsy & Organ Donation

Discussing the options and obtaining consent for autopsy and organ donation with patients prior to death is usually the best practice. This advances the principle of patient autonomy and lessens the responsibilities of distressed family members during the period immediately following the death. After a patient dies, however, designated organ transplant personnel are more successful than the treating clinicians at obtaining consent for organ donation from surviving family members. Federal regulations now require that a designated representative of an organ procurement organization approach the family about organ donation. Most people in the United States support the donation of organs for transplants. Currently, however, organ transplantation is severely limited by the availability of donor organs. Many potential donors and the families of actual donors experience a sense of reward in contributing, even through death, to the lives of others.

Clinicians must be sensitive to ethnic and cultural differences in attitudes about autopsy and organ donation. Patients or their families should be reminded of their right to limit autopsy or organ donation in any way they choose. Pathologists can perform autopsies without interfering with funeral plans or the appearance of the deceased.

The results of an autopsy may help surviving family members (and clinicians) understand the exact cause of a patient's death and foster a sense of closure. A clinician-family conference to review the results of the autopsy provides a good opportunity for clinicians to assess how well families are grieving and to answer questions. Despite the advantages of conducting postmortem examinations, autopsy rates have fallen drastically to less than 15% today. Families report refusing autopsies out of fear of disfigurement of the body or delay of the funeral—or say they were simply not asked. They allow autopsies in order to advance medical knowledge, to identify the exact cause of their loved one's death, and to be reassured that appropriate care was given. Routinely addressing these issues when discussing autopsy may help increase the autopsy rate; the most important mistake is the failure to ask for permission to perform it.

Follow-Up & Grieving

Proper care of patients at the end of life includes following up with surviving family members after the patient has died. Following up by telephone enables the clinician to assuage any guilt about decisions the family may have made, assess how families are grieving, reassure them about the nature of normal grieving, and identify complicated grief or depression. Clinicians can recommend support groups and counseling as needed. A card or telephone call from the clinician to the family days to weeks after the patient's death (and perhaps on the anniversary of the death) allows the clinician to express concern for the family and the deceased.

After a patient dies, the clinician too may need to grieve. Although clinicians may be relatively unaffected by the deaths of some patients, other deaths may cause distressing feelings of sadness, loss, and guilt. These emotions should be recognized as the first step toward processing them or preventing them in the future.

For clinicians, grieving the loss of a patient is normal. Each clinician may find personal or communal resources that help with the process of grieving. Shedding tears, the support of colleagues, time for reflection, and traditional or personal mourning rituals all may be effective. Attending the funeral of a patient who has died can be a satisfying personal experience that is almost universally appreciated by families and that may be the final element in caring well for people at the end of life.

Dermatology: Introduction

Dermatologic diseases are diagnosed by the types of lesions they cause. To make a diagnosis: (1) identify the type of lesion(s) the patient exhibits by morphology establishing a differential diagnosis (Table 6–1); and (2) obtain the elements of the history, physical examination, and appropriate laboratory tests to confirm the diagnosis. Unique clinical situations, such as the ill ICU patient, lead to different diagnostic considerations.

Table 6–1. Morphologic categorization of skin lesions and diseases.

Pigmented	Freckle, lentigo, seborrheic keratosis, nevus, blue nevus, halo nevus, atypical nevus, melanoma
Scaly	Psoriasis, dermatitis (atopic, stasis, seborrheic, chronic allergic contact or irritant contact), xerosis (dry skin), lichen simplex chronicus, tinea, tinea versicolor, secondary

	syphilis, pityriasis rosea, discoid lupus erythematosus, exfoliative dermatitis, actinic keratoses, Bowen disease, Paget disease, intertrigo
Vesicular	Herpes simplex, varicella, herpes zoster, dyshidrosis (vesicular dermatitis of palms and soles), vesicular tinea, dermatophytid, dermatitis herpetiformis, miliaria, scabies, photosensitivity
Weepy or encrusted	Impetigo, acute contact allergic dermatitis, any vesicular dermatitis
Pustular	Acne vulgaris, acne rosacea, folliculitis, candidiasis, miliaria, any vesicular dermatitis
Figurate ("shaped") erythema	Urticaria, erythema multiforme, erythema migrans, cellulitis, erysipelas, erysipeloid, arthropod bites
Bullous	Impetigo, blistering dactylitis, pemphigus, pemphigoid, porphyria cutanea tarda, drug eruptions, erythema multiforme, toxic epidermal necrolysis
Papular	Hyperkeratotic: warts, corns, seborrheic keratoses

	Purple-violet: lichen planus, drug eruptions, Kaposi sarcoma
	Flesh-colored, umbilicated: molluscum contagiosum
	Pearly: basal cell carcinoma, intradermal nevi
	Small, red, inflammatory: acne, miliaria, candidiasis, scabies, folliculitis
Pruritus[1]	Xerosis, scabies, pediculosis, bites, systemic causes, anogenital pruritus
Nodular, cystic	Erythema nodosum, furuncle, cystic acne, follicular (epidermal) inclusion cyst
Photodermatitis (photodistributed rashes)	Drug, polymorphic light eruption, lupus erythematosus
Morbilliform	Drug, viral infection, secondary syphilis
Erosive	Any vesicular dermatitis, impetigo, aphthae, lichen planus, erythema multiforme
Ulcerated	Decubiti, herpes simplex, skin cancers, parasitic infections, syphilis (chancre), chancroid, vasculitis,

	stasis, arterial disease

[1] Not a morphologic class but included because it is one of the most common dermatologic presentations.

Principles of Dermatologic Therapy

Frequently Used Treatment Measures

Bathing

Soap should be used only in the axillae and groin and on the feet by persons with dry or inflamed skin. Soaking in water for 10–15 minutes before applying topical corticosteroids enhances their efficacy. Bath oils can be used, but add little above the use of moisturizers and may make the tub slippery, increasing the risk of falling.

Topical Therapy

Nondermatologists should become familiar with a representative agent in each category for each indication (eg, topical corticosteroid, topical retinoid, etc).

Corticosteroids

Topical corticosteroid creams, lotions, ointments, gels, foams, and sprays are presented in Table 6–2. Topical corticosteroids are divided into classes based on potency. There is little (except price) to recommend one agent over another within the same class. For a given agent, an ointment is more potent than a cream. The potency of a topical corticosteroid may be dramatically increased by applying an occlusive dressing over the corticosteroid. At least 4 hours of occlusion is required to enhance penetration. Such dressings may include gloves, plastic wrap, or plastic occlusive suits for patients with generalized erythroderma or atopy. Caution should be used in applying topical corticosteroids to areas of thin skin (face, scrotum, vulva, skin folds). Topical corticosteroid use on the eyelids may result in glaucoma or cataracts. One may estimate the amount of topical corticosteroid needed by using the "rule of nines" (as in burn evaluation; see Figure 37–2). In general, it takes an average of 20–30 g to cover the body surface of an adult once. Systemic absorption does occur, but adrenal suppression, diabetes, hypertension, osteoporosis, and other complications of systemic corticosteroids are very rare with topical corticosteroid therapy (see photograph); (see photograph).

Table 6–2. Useful topical dermatologic therapeutic agents.

Agent	Formulations, Strengths, and Prices[1]	Apply	Potency Class	Common Indications	Comments
Corticosteroids					
Hydrocortisone acetate	Cream 1%: $3.00/30 g	Twice daily	Low	Seborrheic dermatitis	Not the same as hydrocortisone butyrate or valerate!
	Ointment 1%: $3.00/30 g			Pruritus ani	Not for poison oak!
	Lotion 1%: $7.19/120 mL			Intertrigo	OTC lotion (Aquinil HC)
					OTC solution (Scalpicin, T Scalp)
	Cream	Tw	Low	As for	Perhaps

	2.5%: $12.81/30 g	ice daily		1% hydrocortisone	better for pruritus ani
					Not clearly better than 1%
					More expensive
					Not OTC
Alclometasone dipropionate (Aclovate)	Cream 0.05%: $20.29/15 g	Twice daily	Low	As for hydrocortisone	More efficacious than hydrocortisone
	Ointment 0.05%: $39.70/45 g				Perhaps causes less atrophy
Clocortolone (Cloderm)	Cream 0.1%: $75.00/30 g	Three times daily	Medium	Contact dermatitis	Does not cross react with other corticosteroids chemically and can be used in
				Atopic dermatitis	

					patients allergic to other corticosteroids.
Desonide	Cream 0.05%: $15.47/15 g	Twice daily	Low	As for hydrocortisone	More efficacious than hydrocortisone
	Ointment 0.05%: $39.88/60 g			For lesions on face or body folds resistant to hydrocortisone	Can cause rosacea or atrophy
	Lotion 0.05%: $32.83/60 mL				Not fluorinated
Prednicarbate (Dermatop)	Emollient cream 0.1%: $24.59/15 g	Twice daily	Medium	As for triamcinolone	May cause less atrophy
	Ointment 0.1%: $25.13/1				No generic formulations

	5 g				Preservative-free
Triamcinolone acetonide	Cream 0.1%: $3.60/15 g	Twice daily	Medium	Eczema on extensor areas	Caution in body folds, face
	Ointment 0.1%: $3.60/15 g				Economical in 0.5-lb and 1-lb sizes for treatment of large body surfaces
	Lotion 0.1%: $42.44/60 mL			Used for psoriasis with tar	Economical as solution for scalp
				Seborrheic dermatitis and psoriasis on scalp	
	Cream 0.025%: $3.00/15 g	Twice daily	Medium	As for 0.1% strength	Possibly less efficacy and few

	Ointment 0.025%: $6.25/80 g				advantages over 0.1% formulation

	Solution 8%: $216.01/6.6 mL				
Naftifine (Naftin)	Cream 1%: $77.86/30 g	Once daily	N/A	Dermatophytes	No generic
	Gel 1%: $156.60/				Somewhat more

	60 mL				effective than clotrimazole and miconazole
Terbinafine (Lamisil)	Cream 1%: $8.15/12 g OTC	Once daily	N/A	Dermatophytes	Fast clinical response OTC
Antipruritics					
Camphor/ menthol	Compounded lotion (0.5% of each)	Two to three times daily	N/A	Mild eczema, xerosis, mild contact dermatitis	
Pramoxine hydrochloride (Prax)	Lotion 1%: $15.89/120 mL OTC	Four times daily	N/A	Dry skin, varicella, mild eczema, pruritus ani	OTC formulations (Prax, Aveeno Anti-Itch Cream or Lotion;

					Itch-X Gel)
					By prescription mixed with 1% or 2% hydrocortisone
Doxepin (Zonalon)	Cream 5%: $103.14/ 30 g	Four times daily	N/A	Topical antipruritic, best used in combination with appropriate topical corticosteroid to enhance efficacy	Can cause sedation
Emollients					
Aveeno	Cream, lotion, others	Once to three tim	N/A	Xerosis, eczema	Choice is most often based on personal preference by patient

		es daily			
Aqua glycolic	Cream, lotion, shampoo, others	Once to three times daily	N/A	Xerosis, ichthyosis, keratosis pilaris	Contains 8% glycolic acid
				Mild facial wrinkles	Available from other makers, eg, Alpha Hydrox, or generic 8% glycolic acid lotion
				Mild acne or seborrheic dermatitis	May cause stinging on eczematous skin
Aquaphor	Ointment: $4.99/50 g	Once to three times dail	N/A	Xerosis, eczema	Not as greasy as petrolatum
				For protection of area in pruritus ani	

		y			
Carmol	Lotion 10%: $12.05/180 mL	Twice daily	N/A	Xerosis	Contains urea as humectant
	Cream 20%: $14.63/90 g				Nongreasy hydrating agent (10%); debrides keratin (20%)
Complex 15	Lotion: $6.48/240 mL	Once to three times daily	N/A	XerosisLotion or cream recommended for split or dry nails	Active ingredient is a phospholipid
	Cream: $4.82/75 g				
DML	Cream, lotion, facial moisturizer: $5.95/24	Once to three tim	N/A	As for Complex 15	Face cream has sunscreen

	0 mL	es daily			
Eucerin	Cream: $5.10/120 g	Once to three times daily	N/A	Xerosis, eczema	Many formulations made
	Lotion: $5.10/240 mL				Eucerin Plus contains alphahydroxy acid and may cause stinging on eczematous skin
					Facial moisturizer has SPF 25 sunscreen
Lac-Hydrin-Five	Lotion: $10.54/240 mL OTC	Twice daily	N/A	Xerosis, ichthyosis, keratosis pilaris	Rx product is 12%
Lubriderm	Lotion:	On	N/A	Xerosis,	Unscented

	$7.36/480 mL	ce to three times daily		eczema	usually preferred
Neutrogena	Cream, lotion, facial moisturizer: $7.39/240 mL	Once to three times daily	N/A	Xerosis, eczema	Face cream has titanium-based sunscreen
Ceratopic Cream	Cream: $39.50/4 oz	Twice daily	N/A	Xerosis, eczema	Contains ceramide; anti-inflammatory and non-greasy moisturizer
U-Lactin	Lotion: $7.13/24	Once	N/A	Hyperkeratotic heels	Moisturizes and

	0 mL OTC	daily			removes keratin

[1] Average wholesale price (AWP, for AB-rated generic when available) for quantity listed. AWP may not accurately represent the actual pharmacy cost because wide contractual variations exist among institutions. Source: *Red Book Update*, Vol. 28, No. 3, March 2009.

[2] Topical tacrolimus and pimecrolimus should only be used when other topical treatments are ineffective. Treatment should be limited to an area and duration to be as brief as possible. Treatment with these agents should be avoided in persons with known immunosuppression, HIV infection, bone marrow and organ transplantation, lymphoma, at high risk for lymphoma, and those with a prior history of lymphoma.

N/A, not applicable; OTC, over-the-counter.

Emollients for dry skin ("moisturizers")

Dry skin is not related to water intake but to abnormal function of the epidermis. Many types of emollients are available. Petrolatum, mineral oil, Aquaphor, Vanicream, and Eucerin cream are the heaviest and best. Emollients are most effective when applied to wet skin. If the skin is too greasy after application, pat dry with a damp towel. Vanicream is relatively allergen-free and can be used if allergic contact dermatitis to topical products is suspected.

The scaly appearance of dry skin may be improved by urea, lactic acid, or glycolic acid-containing products provided no inflammation (erythema or pruritus) is present.

Drying agents for weepy dermatoses

If the skin is weepy from infection or inflammation, drying agents may be beneficial. The best drying agent is water, applied as repeated compresses for 15–30 minutes, alone or with aluminum salts (Burow solution, Domeboro tablets) or colloidal oatmeal (Aveeno).

Topical antipruritics

Lotions that contain 0.5% each of camphor and menthol (Sarna) or pramoxine hydrochloride 1%, are effective antipruritic agents (with or without 0.5% menthol, eg, Prax, PrameGel, Aveeno Anti-Itch lotion). Hydrocortisone, 1% or 2.5%, may be incorporated for its anti-inflammatory effect (Pramosone cream, lotion, or ointment). Doxepin cream 5% may reduce pruritus but may cause drowsiness. Pramoxine and doxepin are most effective when applied with topical corticosteroids. Monoamine oxidase inhibitors should be discontinued at least 2 weeks before treatment with doxepin.

Systemic antipruritic drugs

Antihistamines

H_1-blockers are the agents of choice for pruritus when due to histamine, such as in urticaria. Otherwise, they appear to relieve pruritus only by their sedating effects. Except in the case of urticaria, nonsedating antihistamines are of limited value in inflammatory skin diseases.

Hydroxyzine 25–50 mg nightly is typically used for its sedative effect in pruritic diseases. Sedation can limit daytime use. The least sedating antihistamines are loratadine and fexofenadine. Cetirizine causes drowsiness in about 15% of patients. Some antidepressants, such as doxepin, mirtazapine, sertraline, and paroxetine can be effective antipruritics.

Systemic corticosteroids

(See Chapter 26: Endocrine Disorders.)

Sunscreens

Protection from ultraviolet light should begin at birth and will reduce the incidence of actinic keratoses and some nonmelanoma skin cancers when initiated at any age. The best protection is shade, but protective clothing, avoidance of direct sun exposure during the peak hours of the day, and daily use of chemical sunscreens are important.

Fair-complexioned persons should use a sunscreen with an SPF (sun protective factor) of at least 15 and preferably 30–40 every day. Sunscreens with high SPF values (> 30) afford some protection against UVA as well as UVB and may be helpful in managing photosensitivity disorders. Physical blockers (titanium dioxide and zinc oxide) are available in vanishing formulations. Aggressive sunscreen use should be accompanied by vitamin D supplementation in persons at risk for osteopenia (eg, organ transplant recipients).

Complications of Topical Dermatologic Therapy

Complications of topical therapy can be largely avoided.

They fall into several categories:

Allergy

Of the topical antibiotics, neomycin and bacitracin have the greatest potential for sensitization. Diphenhydramine, benzocaine, vitamin E, aromatic essential oils, and bee pollen are potential sensitizers in topical medications. Preservatives and even the topical corticosteroids themselves can cause allergic contact dermatitis.

Irritation

Preparations of tretinoin, benzoyl peroxide, and other acne medications should be applied sparingly to the skin.

Overuse

Topical corticosteroids may induce acne-like lesions on the face (steroid rosacea) and atrophic striae in body folds.

Melanocytic Nevi (Normal Moles)

In general, a **benign mole** is a small (< 6 mm) lesion with a well-defined border and a single shade of pigment from beige or pink to dark brown (see photograph). The physical examination must take precedence over the history.

Fig.

Normal mole (nevus). (Reproduced, with permission, from Bondi EE, Jegasothy BV, Lazarus GS [editors]: *Dermatology: Diagnosis & Treatment*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Moles have a normal natural history. In the patient's first decade of life, moles often appear as flat, small, brown lesions. They are called **junctional nevi** because the nevus cells are at the junction of the epidermis and dermis. Over the next 2 decades, these moles grow in size and often become raised, reflecting the appearance of a dermal component, giving rise to **compound nevi** (Plate 1). Moles may darken and grow during pregnancy. As white patients enter their seventh and eighth decades, most moles have lost their junctional component and dark pigmentation. At every stage of life, normal moles should be well-demarcated, symmetric, and uniform in contour and color.

Plate 1.

Benign, flat and macular compound nevus on the arm. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

Bishop JN et al. The prevention, diagnosis, referral and management of melanoma of the skin: concise guidelines. Clin Med. 2007 Jun;7(3):283–90. [PMID: 17633952]

Atypical Nevi

The term "atypical nevus" or "atypical mole" has supplanted "dysplastic nevus." The diagnosis of atypical moles is made clinically and not histologically, and moles should be removed only if they are suspected to be melanomas. Clinically, these moles are large (6 mm in diameter), with an ill-defined, irregular border and irregularly distributed pigmentation (Plate 2) (see photograph). It is estimated that 5–10% of the white population in the United States has one or more atypical nevi. Studies have defined an increased risk of melanoma in the following populations: patients with 50 or more nevi with one or more atypical moles and one mole at least 8 mm or larger, and patients with a few to many definitely atypical moles. These patients deserve education and regular (usually every 6–12 months) follow-up. Kindreds with familial melanoma (numerous atypical nevi and a strong family history) deserve even closer attention, as the risk of developing single or even multiple melanomas in these individuals approaches 50% by age 50.

Plate 2.

atypical nevus patients. J Am Acad Dermatol. 2007 May;56(5):748–52. [PMID: 17276542]

Blue Nevi

Blue nevi are small, slightly elevated, blue-black lesions that favor the dorsal hands (Plate 3). They are common in persons of Asian descent, and an individual patient may have several of them. If present without change for many years, they may be considered benign, since malignant blue nevi are rare. However, blue-black papules and nodules that are new or growing must be evaluated to rule out nodular melanoma.

Plate 3.

Blue nevus on the left cheek, with some resemblance to a melanoma. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

Freckles & Lentigines

Freckles (ephelides) and lentigines are flat brown spots (see photograph); (see photograph). Freckles first appear in young children, darken with ultraviolet exposure, and fade with cessation of sun exposure. In adults, flat brown spots (lentigines) gradually appear in sun-exposed areas, particularly the dorsa of the hands. They do not fade with cessation of sun exposure. They should be evaluated like all pigmented lesions: If the pigmentation is homogeneous and they are symmetric and flat, they are most likely benign. They can be treated with topical 0.1% tretinoin, tazarotene 0.1%, 2% 4-hydroxyanisole with tretinoin 0.01% (Solage), laser therapy, and cryotherapy.

Acad Dermatol. 2006 May;54(5 Suppl 2):S262–71. [PMID: 16631967]

Seborrheic Keratoses

Seborrheic keratoses are benign plaques, beige to brown or even black, 3–20 mm in diameter, with a velvety or warty surface (Plate 4) (see photograph). They appear to be stuck or pasted onto the skin. They are extremely common—especially in the elderly—and may be mistaken for melanomas or other types of cutaneous neoplasms. Although they may be frozen with liquid nitrogen or curetted if they itch or are inflamed, no treatment is needed.

Plate 4.

Seborrheic keratosis with "stuck on appearance" but irregular borders and color variation suspicious for possible melanoma. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

Malignant Melanoma

Essentials of Diagnosis

- May be flat or raised.
- Should be suspected in any pigmented skin lesion with recent change in appearance.
- Examination with good light may show varying colors, including red, white, black, and bluish.
- Borders typically irregular.

General Considerations

Malignant melanoma is the leading cause of death due to skin disease. There were an estimated 59,940 new cases of melanoma in the United States in 2007, with 8110 deaths. One in four cases of melanoma occurs before the age of 40. Overall survival for melanomas in whites has risen from 60% in 1960–1963 to more than 85% currently, primarily due to earlier detection of lesions.

Tumor thickness is the single most important prognostic factor. Ten-year survival rates—related to thickness in millimeters—are as follows: < 1 mm, 95%; 1–2 mm, 80%; 2–4 mm, 55%; and > 4 mm, 30%. With lymph node involvement, the 5-year survival rate is 30%; with distant metastases, it is less than 10%.

Clinical Findings

Primary malignant melanomas may be classified into various clinicohistologic types, including lentigo maligna melanoma (arising on chronically sun-exposed skin of older individuals); superficial spreading malignant melanoma (two-thirds of all melanomas arising on intermittently sun-exposed skin); nodular malignant melanoma; acral-lentiginous melanomas (arising on palms, soles, and nail beds); and malignant melanomas on mucous membranes. Clinical features of pigmented lesions suspicious for melanoma are an irregular notched border where the pigment appears to be leaking into the normal surrounding skin; a topography that may be irregular, ie, partly raised and partly flat (Plates 5 and 6). Color variegation is present, and colors such as pink, blue, gray, white, and black are indications for referral. A useful mnemonic is the ABCD rule: "ABCD = Asymmetry, Border irregularity, Color variegation, and Diameter greater than 6 mm." "E" for Evolution can be added. The history of a changing mole (evolution) is the single most important historical reason for close evaluation and possible referral. Bleeding and ulceration are ominous signs. A mole that stands out from the patient's other moles deserves special scrutiny—the "ugly duckling sign." A patient with a large number of moles is statistically at increased risk for melanoma and deserves careful and periodic examination, particularly if the lesions are atypical. Referral of suspicious pigmented lesions is always appropriate.

Plate 5.

Plate 6.
Melanoma resembling a seborrheic keratosis on the

lateral face of a man. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

While superficial spreading melanoma is largely a disease of whites, persons of other races are at risk for other types of melanoma, particularly acral lentiginous melanoma. These occur as dark, sometimes irregularly shaped lesions on the palms and soles and as new, often broad and solitary, darkly pigmented longitudinal streaks in the nails. Acral lentiginous melanoma may be a difficult diagnosis because benign pigmented lesions of the hands, feet, and nails occur commonly in more darkly pigmented persons and clinicians may hesitate to biopsy the palms, soles, and nail beds. As a result, the diagnosis is often delayed until the tumor has become clinically obvious and histologically thick. Clinicians should give special attention to new or changing lesions in these areas.

Dermoscopy—use of a special magnifying device to evaluate pigmented lesions—helps select suspicious lesions that require biopsy. In experienced hands, the specificity is 85% and the sensitivity 95%.

Fig.

Superficial spreading malignant melanoma. (Reproduced, with permission, from Bondi EE, Jegasothy BV, Lazarus GS [editors]: *Dermatology: Diagnosis & Treatment*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Treatment

Treatment of melanoma consists of excision. After histologic diagnosis, the area is usually reexcised with margins dictated by the thickness of the tumor. Thin low-risk and intermediate-risk tumors require only conservative margins of 1–3 cm. More specifically, surgical margins of 0.5 cm for melanoma in situ and 1 cm for lesions less than 1 mm in thickness are recommended.

Sentinel lymph node biopsy (selective lymphadenectomy) using preoperative lymphoscintigraphy and intraoperative lymphatic mapping is effective for staging melanoma patients with intermediate risk without clinical adenopathy and is recommended for all patients with lesions over 1 mm in thickness or with high-risk histologic features. Referral of intermediate-risk and high-risk patients to centers with expertise in melanoma is strongly recommended.

Atopic Dermatitis (Eczema)

Essentials of Diagnosis

- Pruritic, exudative, or lichenified eruption on face, neck, upper trunk, wrists, and hands and in the antecubital and popliteal folds.
- Personal or family history of allergic manifestations (eg, asthma, allergic rhinitis, atopic dermatitis).
- Tendency to recur.
- Onset in childhood in most patients. Onset after age 30 is very uncommon.

General Considerations

Atopic dermatitis looks different at different ages and in people of different races. Diagnostic criteria for atopic dermatitis must include pruritus, typical morphology and distribution (flexural lichenification, hand eczema, nipple eczema, and eyelid eczema in adults), onset in childhood, and chronicity. Also helpful are (1) a personal or family history of atopic disease (asthma, allergic rhinitis, atopic dermatitis), (2) xerosis-ichthyosis, (3) facial pallor with infraorbital darkening, (4) elevated serum IgE, and (5) repeated skin infections.

Clinical Findings

Symptoms and Signs

Itching may be severe and prolonged. Rough, red plaques usually without the thick scale and discrete demarcation of psoriasis (see photograph) affect the face, neck, and upper trunk. The flexural surfaces of elbows and knees are often involved. In chronic cases, the skin is dry, leathery, and lichenified (see photograph). Pigmented persons may have poorly demarcated hypopigmented patches (pityriasis alba) on the cheeks and extremities (see photograph). In black patients with severe disease, pigmentation may be lost in lichenified areas. During acute flares, widespread redness with weeping, either diffusely or in discrete plaques, is common.

Laboratory Findings

Food allergy is an uncommon cause of flares of atopic dermatitis in adults. Radioallergosorbent tests (RASTs) or skin tests may suggest dust mite allergy. Eosinophilia and increased serum IgE levels may be present.

Differential Diagnosis

Atopic dermatitis must be distinguished from seborrheic dermatitis (less pruritic, frequent scalp and face involvement, greasy and scaly lesions, and quick response to therapy). Secondary staphylococcal infections may exacerbate atopic dermatitis, and should be considered during hyperacute, weepy flares of atopic dermatitis (see photograph)(see photograph). Since virtually all patients with atopic dermatitis have skin disease before age 5, a new diagnosis of atopic dermatitis in an adult over age 30 should be made cautiously and only after consultation. Atopic-like dermatitis associated with marked elevation of IgE; recurrent, sometimes cold, staphylococcal abscesses; recurrent pneumonia with pneumatocele formation; and retained primary dentition may indicate hyper-IgE syndrome.

Fig.

Impetiginization of atopic dermatitus was suspected in this patient when his lesions developed a crusty, weepy character. (Courtesy of S Goldstein.)

Treatment

Patient education regarding gentle skin care and exactly how to use medications is critical in the successful management of atopic dermatitis.

General Measures

Atopic patients have hyperirritable skin. Anything that dries or irritates the skin will potentially trigger dermatitis. Atopic individuals are sensitive to low humidity and often get worse in the winter. Adults with atopic disorders should not bathe more than once daily. Soap should be confined to the armpits, groin, scalp and feet. Washcloths and brushes should not be used. After rinsing, the skin should be patted dry (not rubbed) and then immediately—within three minutes—covered with a thin film of an emollient such as Aquaphor, Eucerin, petrolatum, Vanicream, or a corticosteroid as needed. Vanicream can be used if contact dermatitis resulting from additives in medication is suspected. Atopic patients may be irritated by scratchy fabrics, including wools and acrylics. Cottons are preferable, but synthetic blends also are tolerated. Other triggers of eczema in some patients include sweating, ointments, hot baths, and animal danders. In adults, food allergy is a very uncommon cause of atopic dermatitis or its flares.

Local Treatment

Corticosteroids should be applied sparingly to the dermatitis once or twice daily and rubbed in well. Their potency should be appropriate to the severity of the dermatitis. In general, one should begin with triamcinolone 0.1% or a stronger corticosteroid then taper to hydrocortisone or another slightly stronger mild corticosteroid (alclometasone, desonide). It is vital that patients taper off corticosteroids and substitute emollients as the dermatitis clears to avoid the side effects of corticosteroids. Tapering is also important to avoid rebound flares of the dermatitis that may follow their abrupt cessation. Tacrolimus ointment (Protopic 0.03% or 0.1%) and pimecrolimus cream (Elidel 1%) can be effective in managing atopic dermatitis when applied twice daily. Burning on application occurs in about 50% of patients using Protopic and in 10–25% of Elidel users, but it may resolve with continued treatment. These medications do not appear to cause skin atrophy or striae, and are safe for application on the face and even the eyelids.

The US Food and Drug Administration (FDA) has issued a black box warning for both topical tacrolimus and pimecrolimus due to concerns about the development of T-cell lymphoma. The agents should be used sparingly and only in locations where less expensive corticosteroids cannot be used. Tacrolimus and pimecrolimus should be avoided in patients at high risk for lymphoma (ie, those with HIV, iatrogenic immunosuppression, prior lymphoma). The treatment of atopic dermatitis is dictated by the stage of the dermatitis.

Acute weeping lesions

(See photograph.) Use water or aluminum subacetate solution (Domeboro tablets, one in a pint of cool water) or colloidal oatmeal (Aveeno; dispense one box, and use as directed on box) as soothing or astringent soaks, baths, or wet dressings for 10–30 minutes two to four times daily. Lesions on extremities particularly may be bandaged for protection at night. Use high-potency corticosteroids after soaking but spare the face and body folds. Tacrolimus is usually not tolerated at this stage. Systemic corticosteroids may be required (see below).

Fig.

Vesicular eczema. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Subacute or scaly lesions

(See photograph.) At this stage, the lesions are dry but still red and pruritic. Mid- to high-potency corticosteroids in ointment form should be continued until scaling and elevated skin lesions are cleared and itching is decreased substantially. At that point, patients should begin a 2- to 4-week taper from twice-daily to daily to alternate-day dosing with topical corticosteroids to reliance on emollients, with occasional use of corticosteroids on specific itchy areas. Instead of tapering the frequency of usage of a more potent corticosteroid, it may be preferable to switch to a low-potency corticosteroid. Tacrolimus and pimecrolimus are more expensive alternatives and may be added if corticosteroids cannot be stopped. They avoid the complications of long-term topical corticosteroid use.

Fig.

Patchy atopic dermatitis on the thighs. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Chronic, dry, lichenified lesions

Thickened and usually well-demarcated, they are best treated with high-potency to ultra-high-potency corticosteroid ointments. Nightly occlusion for 2–6 weeks may enhance the initial response. Occasionally, adding tar preparations such as LCD (liquor carbonis detergens) 10% in Aquaphor or 2% crude coal tar may be beneficial.

Maintenance treatment

Once symptoms have improved, constant application of effective moisturizers is recommended to prevent flares. In patients with moderate disease, weekend only use of topical corticosteroids can prevent flares.

Systemic and Adjuvant Therapy

Systemic corticosteroids are indicated only for severe acute exacerbations. Oral prednisone dosages should be high enough to suppress the dermatitis quickly, usually starting with 40–60 mg daily for adults. The dosage is then tapered to nil over a period of 2–4 weeks. Owing to the chronic nature of atopic dermatitis and the side effects of chronic systemic corticosteroids, long-term use of these agents is not recommended for maintenance therapy. Classic antihistamines may relieve severe pruritus. Hydroxyzine, diphenhydramine, or doxepin may be useful—the dosage increased gradually to avoid drowsiness. Fissures, crusts, erosions, or pustules indicate staphylococcal infection clinically. Antistaphylococcal antibiotics given systemically—such as a first-generation cephalosporin—may be helpful in management. Cultures to exclude methicillin-resistant *Staphylococcus aureus* are recommended. Phototherapy can be an important adjunct for severely affected patients, and the properly selected patient with recalcitrant disease may benefit greatly from therapy with UVB with or without coal tar or PUVA (psoralen plus ultraviolet A). Oral cyclosporine, mycophenolate mofetil, or azathioprine may be used for the most severe and recalcitrant cases.

Complications of Treatment

The clinician should monitor for skin atrophy. **Eczema herpeticum,** a generalized herpes simplex infection manifested by monomorphic vesicles, crusts, or scalloped erosions superimposed on atopic dermatitis or other extensive eczematous processes, is treated successfully with oral acyclovir, 200 mg five times daily, or intravenous acyclovir in a dose of 10 mg/kg intravenously every 8 hours (500 mg/m^2 every 8 hours) (see photograph). Tacrolimus and pimecrolimus may increase the risk of eczema herpeticum.

Fig.

A patch of eczema herpeticum composed of umbilicated vesicles with central large erosion. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Smallpox vaccination is absolutely contraindicated in patients with atopic dermatitis or a history thereof because of the risk of eczema vaccinatum. Generalized vaccinia may develop in patients with atopic dermatitis who have contact with recent vaccine recipients who still have pustular or crusted vaccination sites. Eczema vaccinatum and generalized vaccinia are indications for vaccinia immune globulin.

Prognosis

Atopic dermatitis runs a chronic or intermittent course. Affected adults may have only hand dermatitis. Poor prognostic factors for persistence into adulthood in atopic dermatitis include onset early in childhood, early generalized disease, and asthma. Only 40–60% of these patients have lasting remissions.

Lichen Simplex Chronicus (Circumscribed Neurodermatitis)

Essentials of Diagnosis

- Chronic itching and scratching.
- Lichenified lesions with exaggerated skin lines overlying a thickened, well-circumscribed scaly plaque.
- Predilection for nape of neck, wrists, external surfaces of forearms, lower legs, scrotum, and vulva.

General Considerations

Lichen simplex chronicus represents a self-perpetuating scratch-itch cycle—a learned behavior that is hard to disrupt.

Clinical Findings

Intermittent itching incites the patient to scratch the lesions. Itching may be so intense as to interfere with sleep. Dry, leathery, hypertrophic, lichenified plaques appear on the neck, ankles, or perineum (Plate 7) (see photograph). The patches are rectangular, thickened, and hyperpigmented. The skin lines are exaggerated.

Plate 7.

Lichen simplex chronicus. (Used, with permission, from Berger TG, Dept. Dermatology, UCSF.)

Fig.

Lichen simplex chronicus resulting from repeated itch-scratch cycles. Note the hypertrophic leathery, lichenified plaques. The exaggerated skin lines are characteristic. (Courtesy of S Goldstein.)

Differential Diagnosis

This disorder can be differentiated from plaque-like lesions such as psoriasis (redder lesions having whiter scales on the elbows, knees, and scalp and nail findings) (see photograph), lichen planus (violaceous, usually smaller polygonal papules), and nummular (coin-shaped) dermatitis (see photograph). Lichen simplex chronicus may complicate chronic atopic dermatitis.

Fig.

Nummular dermatitis presents as more acute round, scaly, or moist lesions without marked lichenification. (Courtesy of S Goldstein.)

Treatment

For lesions in extra-genital regions, superpotent topical corticosteroids are effective, with or without occlusion, when used twice daily for several weeks. In some patients, flurandrenolide (Cordran) tape may be effective, since it prevents scratching and rubbing of the lesion. The injection of triamcinolone acetonide suspension (5–10 mg/mL) into the lesions may occasionally be curative. Continuous occlusion with a flexible hydrocolloid dressing for 7 days at a time for 1–2 months may also be helpful. The area should be protected and the patient encouraged to become aware of when he or she is scratching. For genital lesions, see the section Anogenital Pruritus.

Prognosis

The disease tends to remit during treatment but may recur or develop at another site.

Psoriasis

Essentials of Diagnosis

- Silvery scales on bright red, well-demarcated plaques, usually on the knees, elbows, and scalp.
- Nail findings including pitting and onycholysis (separation of the nail plate from the bed).
- Mild itching (usually).
- May be associated with psoriatic arthritis.
- Histopathology is not often useful and can be confusing.

General Considerations

Psoriasis is a common benign, chronic inflammatory skin disease with a genetic basis. Injury or irritation of normal skin tends to induce lesions of psoriasis at the site (Koebner phenomenon) (see photograph); (see photograph). Psoriasis has several variants—the most common is the plaque type (see photograph); (see photograph); (see photograph). Eruptive (guttate) psoriasis consisting of myriad lesions 3–10 mm in diameter occurs occasionally after streptococcal pharyngitis. Rarely, grave, occasionally life-threatening forms (generalized pustular and erythrodermic psoriasis) may occur. Plaque type or extensive erythrodermic psoriasis with abrupt onset may accompany HIV infection.

Fig.

A, B: Plaque-like psoriasis of the scalp with characteristic silvery, thick scale distinguishes it from seborrheic dermatitis of the scalp. (Courtesy of S Goldstein.)

Clinical Findings

There are often no symptoms, but itching may occur and be severe. Favored sites include the scalp, elbows, knees, palms and soles, and nails (Plate 8). The lesions are red, sharply defined plaques covered with silvery scales (Plate 9). The glans penis and vulva may be affected. Occasionally, only the flexures (axillae, inguinal areas) are involved. Fine stippling ("pitting") in the nails is highly suggestive of psoriasis (see photograph); (see photograph). Patients with psoriasis often have a pink or red intergluteal fold. Not all patients have findings in all locations, but the occurrence of a few may help make the diagnosis when other lesions are not typical. Some patients have mainly hand or foot dermatitis and only minimal findings elsewhere. There may be associated arthritis that is most commonly distal and oligoarticular, although the rheumatoid variety with a negative rheumatoid factor may occur (see photograph). The psychosocial impact of psoriasis is a major factor in determining the treatment of the patient.

Fig.

Pitting psoriasis. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Differential Diagnosis

The combination of red plaques with silvery scales on elbows and knees, with scaliness in the scalp or nail findings, is diagnostic (Plate 8). Psoriasis lesions are well demarcated and affect extensor surfaces—in contrast to atopic dermatitis, with poorly demarcated plaques in flexural distribution (see photograph). In body folds, scraping and culture for *Candida* and examination of scalp and nails will distinguish psoriasis from intertrigo and candidiasis (see photograph). Dystrophic changes in nails may simulate onychomycosis, but again, the general examination combined with a potassium hydroxide (KOH) or fungal culture will be valuable in diagnosis (see photograph). The cutaneous features of reactive arthritis (Reiter syndrome) mimic psoriasis.

Intertrigo involving the axillary fold of an infant. (Courtesy of K Zipperstein.)

Fig.

Onychomycosis involving digits 1, 2, and 5. (Courtesy of K Zipperstein.)

Treatment

There are many therapeutic options in psoriasis to be chosen according to the extent (BSA affected) and the presence of other findings (for example, arthritis). Certain drugs, such as -blockers, antimalarials, statins, and lithium, may flare or worsen psoriasis. Even tiny doses of systemic corticosteroids given to patients with psoriasis may lead to severe rebound flares of their disease. Never use systemic corticosteroids to treat flares of psoriasis. In general, patients with moderate to severe psoriasis should be managed by or in conjunction with a dermatologist.

Limited Disease

For patients with limited disease (less than 10% of the patient's BSA), in whom lesions are composed of small plaques, phototherapy is the best therapy (see below). For patients with large plaques, the easiest regimen is to use a high-potency to ultra-high-potency topical corticosteroid cream or ointment. It is best to restrict the ultra-high-potency corticosteroids to 2–3 weeks of twice-daily use and then use them in a pulse fashion three or four times on weekends or switch to a midpotency corticosteroid. Topical corticosteroids rarely induce a lasting remission. They may cause psoriasis to become unstable. Additional measures are therefore commonly added to topical corticosteroid therapy. Calcipotriene ointment 0.005%, a vitamin D analog, is used twice daily for plaque psoriasis. Initially, patients are treated with twice-daily corticosteroids plus calcipotriene twice daily. This rapidly clears the lesions. Calcipotriene is then used alone once daily and with the corticosteroid once daily for several weeks. Eventually, the topical corticosteroids are stopped, and once- or twice-daily calcipotriene is continued long-term. Calcipotriene usually cannot be applied to the groin or on the face because of irritation. Treatment of extensive psoriasis with calcipotriene may result in hypercalcemia. Calcipotriene is incompatible with many topical corticosteroids (but not halobetasol), so if used concurrently it must be applied at a different time. Tar preparations such as Fototar cream, LCD (liquor carbonis detergens) 10% in Nutraderm lotion, alone or mixed directly with triamcinolone 0.1%, are useful adjuncts when applied twice daily. Occlusion alone has been shown to clear isolated plaques in 30–40% of patients. Occlusive hydrocolloid dressings such as thin DuoDerm are placed on the lesions and left undisturbed for as long as possible (a minimum of 5 days, up to 7 days) and then replaced. Responses may be seen within several weeks.

For the scalp, start with a tar shampoo, used daily if possible. For thick scales, use 6%salicylic acid gel (eg, Keralyt), P & S solution (phenol, mineral oil, and glycerin), or fluocinolone acetonide 0.01% in oil (Derma-Smoothe/FS) under a shower cap at night, and shampoo in the morning. In order of increasing potency, triamcinolone 0.1%, or fluocinolone, betamethasone dipropionate, fluocinonide or amcinonide, and clobetasol are available in solution form for use on the scalp twice daily. For psoriasis in the body folds, treatment is difficult, since potent corticosteroids cannot be used and other agents are poorly tolerated. Tacrolimus ointment 0.1% or 0.03 % or pimecrolimus cream 1% may be effective in penile, groin, and facial psoriasis.

Moderate Disease

Psoriasis affecting 10–30% of the patient's BSA is frequently treated with UV phototherapy, either in a medical office or via a home light unit. Systemic agents listed below may also be used.

Generalized Disease

If psoriasis involves more than 30% of the body surface, it is difficult to treat with topical agents. The treatment of choice is outpatient narrowband UVB (NB-UVB) three times weekly. Clearing occurs in an average of 7 weeks, but maintenance may be required. Severe psoriasis unresponsive to outpatient ultraviolet light may be treated in a psoriasis day care center with the Goeckerman regimen, which involves use of crude coal tar for many hours and exposure to UVB light. Such treatment may offer the best chance for prolonged remissions.

PUVA may be effective even in patients who have not responded to standard NB-UVB treatment. Long-term use of PUVA is associated with an increased risk of skin cancer (especially squamous cell carcinoma and perhaps melanoma), particularly in persons with fair complexions. Thus, periodic examination of the skin is imperative. Atypical lentigines are a common complication. There can be rapid aging of the skin in fair individuals. Cataracts have not been reported with proper use of protective glasses. PUVA may be used in combination with other therapy, such as acitretin or methotrexate.

Methotrexate is very effective for severe psoriasis in doses up to 25 mg once weekly. It should be used according to published protocols. Liver biopsy is performed initially after methotrexate has been used long enough by the patient to demonstrate that it is effective and well tolerated, and then at intervals depending on the cumulative dose, usually every 1.5–2 g. Administration of folic acid, 1–2 mg daily, will eliminate nausea caused by methotrexate without compromising efficacy.

Acitretin, a synthetic retinoid, is most effective for pustular psoriasis in dosages of 0.5–0.75 mg/kg/d, but it also improves erythrodermic and plaque types and psoriatic arthritis. Liver enzymes and serum lipids must be checked periodically. Because acitretin is a teratogen and persists for long periods in fat, women of childbearing age must wait at least 3 years after completing acitretin treatment before considering pregnancy. When used as single agents, retinoids will flatten psoriatic plaques, but will rarely result in complete clearing. Retinoids find their greatest use when combined with phototherapy—either UVB or PUVA, with which they are synergistic.

Cyclosporine dramatically improves psoriasis and may be used to control severe cases. Rapid relapse (rebound) is the rule after cessation of therapy, so another agent must be added if cyclosporine is stopped. The tumor necrosis factor (TNF) inhibitors etanercept (Enbrel), 50 mg twice weekly; infliximab (Remicade); and adalimumab (Humira) have shown antipsoriatic activity. Infliximab provides the most rapid response and can be used for severe pustular or erythrodermic flares. Etanercept is used more frequently for long-term treatment at a dose of 50 mg twice weekly for 3 months, then 25 mg twice weekly. All three TNF inhibitors can also induce psoriasis. Alefacept (Amevive) and efalizumab (Raptiva) have moderate efficacy. The role of the latter two immunomodulators is unclear. IL-12/23 monoclonal antibodies can be dramatically effective in psoriasis.

Prognosis

The course tends to be chronic and unpredictable, and the disease may be refractory to treatment.

Pityriasis Rosea

Essentials of Diagnosis

- Oval, fawn-colored, scaly eruption following cleavage lines of trunk.
- Herald patch precedes eruption by 1–2 weeks.
- Occasional pruritus.

General Considerations

This is a common mild, acute inflammatory disease that is 50% more common in females. Young adults are principally affected, mostly in the spring or fall. Concurrent household cases have been reported.

Clinical Findings

Itching is common but is usually mild. The diagnosis is made by finding one or more classic lesions. The lesions consist of oval, fawn-colored plaques up to 2 cm in diameter (Plate 10); (see photograph). The centers of the lesions have a crinkled or "cigarette paper" appearance and a collarette scale, ie, a thin bit of scale that is bound at the periphery and free in the center. Only a few lesions in the eruption may have this characteristic appearance, however. Lesions follow cleavage lines on the trunk (so-called Christmas tree pattern, Plate 11), and the proximal portions of the extremities are often involved. A variant that affects the flexures (axillae and groin), so-called inverse pityriasis rosea, and a papular variant, especially in black patients, also occur. An initial lesion ("herald patch") that is often larger than the later lesions often precedes the general eruption by 1–2 weeks. The eruption usually lasts 6–8 weeks and heals without scarring.

Differential Diagnosis

A serologic test for syphilis should be performed if at least a few perfectly typical lesions are not present and especially if there are palmar and plantar or mucous membrane lesions or adenopathy, features that are suggestive of secondary syphilis (see photograph); (see photograph); (see photograph). For the nonexpert, an RPR (rapid plasma reagin) test in all cases is not unreasonable. Tinea corporis may present with red, slightly scaly plaques, but rarely are there more than a few lesions of tinea corporis compared to the many lesions of pityriasis rosea (see photograph). Seborrheic dermatitis on occasion presents on the body with poorly demarcated patches over the sternum, in the pubic area, and in the axillae (see photograph). Tinea versicolor, viral exanthems, and drug eruptions may simulate pityriasis rosea (see photograph).

Treatment

Pityriasis rosea often requires no treatment. In Asians, Hispanics, or blacks, in whom lesions may remain hyperpigmented for some time, more aggressive management may be indicated. Treatment is, otherwise, only indicated if the patient is symptomatic. No treatment has been demonstrated efficacious in pityriasis rosea in adequately controlled and reproduced trials. Most dermatologists recommend UVB treatments, or prednisone as used for contact dermatitis for severe or severely symptomatic cases. For mild to moderate cases, topical corticosteroids of medium strength (triamcinolone 0.1%) and oral antihistamines may also be used if pruritus is bothersome. Oral erythromycin for 14 days was reported to clear 73% of patients within 2 weeks (compared with none of the patients receiving placebo).

Prognosis

Pityriasis rosea is usually an acute self-limiting illness that disappears in about 6 weeks.

Chuh AA et al. Interventions for pityriasis rosea. Cochrane Database Syst Rev. 2007 Apr

18;(2):CD005068. [PMID: 17443568]

Seborrheic Dermatitis & Dandruff

Essentials of Diagnosis

- Dry scales and underlying erythema.
- Scalp, central face, presternal, interscapular areas, umbilicus, and body folds.

General Considerations

Seborrheic dermatitis is an acute or chronic papulosquamous dermatitis that often coexists with psoriasis.

Clinical Findings

Pruritus is an inconstant finding. The scalp, face, chest, back, umbilicus, eyelid margins, and body folds have dry scales or oily yellowish scurf (Plate 12) (see photograph); (see photograph); (see photograph). Patients with Parkinson disease, HIV infection, and patients who become acutely ill and are hospitalized often have seborrheic dermatitis.

Plate 12.

from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Differential Diagnosis

There is a spectrum from seborrheic dermatitis to scalp psoriasis (see photograph); (see photograph). Extensive seborrheic dermatitis may simulate intertrigo in flexural areas, but scalp, face, and sternal involvement suggests seborrheic dermatitis.

Treatment

Seborrhea of the Scalp

Shampoos that contain zinc pyrithione or selenium are used daily if possible. These may be alternated with ketoconazole shampoo (1% or 2%) used twice weekly. A combination of shampoos is used in refractory cases. Tar shampoos are also effective for milder cases and for scalp psoriasis. Topical corticosteroid solutions or lotions are then added if necessary and are used twice daily. (See treatment for scalp psoriasis.)

Facial Seborrheic Dermatitis

The mainstay of therapy is a mild corticosteroid (hydrocortisone 1%, alclometasone, desonide) used intermittently and not near the eyes. If the disorder cannot be controlled with intermittent use of a mild topical corticosteroid alone, ketoconazole (Nizoral) 2% cream is added twice daily. Topical tacrolimus (Protopic) and pimecrolimus (Elidel) are steroid-sparing alternatives.

Seborrheic Dermatitis of Nonhairy Areas

Low-potency corticosteroid creams—ie, 1% or 2.5% hydrocortisone, desonide, or alclometasone dipropionate—are highly effective.

Seborrhea of Intertriginous Areas

Apply low-potency corticosteroid lotions or creams twice daily for 5–7 days and then once or twice weekly for maintenance as necessary. Ketoconazole or clotrimazole cream may be a useful adjunct. Tacrolimus or pimecrolimus topically may avoid corticosteroid atrophy in chronic cases.

Involvement of Eyelid Margins

"Marginal blepharitis" usually responds to gentle cleaning of the lid margins nightly as needed, with undiluted Johnson and Johnson Baby Shampoo using a cotton swab.

Prognosis

The tendency is for lifelong recurrences. Individual outbreaks may last weeks, months, or years.

Schwartz RA et al. Seborrheic dermatitis: an overview. Am Fam Physician. 2006 Jul 1;74(1):125–30. [PMID: 16848386]

Fungal Infections: Introduction

Mycotic infections are traditionally divided into two principal groups—superficial and deep. In this chapter, we will discuss only the superficial infections: tinea corporis and tinea cruris; dermatophytosis of the feet and dermatophytid of the hands; tinea unguium (onychomycosis); and tinea versicolor. See Chapter 36: Mycotic Infections for discussion of deep mycoses.

The diagnosis of fungal infections of the skin is usually based on the location and characteristics of the lesions and on the following laboratory examinations: (1) Direct demonstration of fungi in 10% KOH of scrapings from suspected lesions. "If it's scaly, scrape it" is a time-honored maxim (see micrograph). (2) Cultures of organisms from skin scrapings. (3) Histologic sections of biopsies stained with periodic acid-Schiff (Hotchkiss-McManus) technique may be diagnostic if scrapings and cultures are negative.

Fig.

(Reproduced, with permission, from Bondi EE, Jegasothy BV, Lazarus GS [editors]: *Dermatology: Diagnosis & Treatment*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Principles of Treatment

A diagnosis should always be confirmed by KOH preparation, culture, or biopsy. Many other diseases cause scaling, and use of an antifungal agent without a firm diagnosis makes subsequent diagnosis more difficult. In general, fungal infections are treated topically except for those involving the nails, those that are very extensive, or those that involve the hair follicles.

Griseofulvin is safe and effective for treating dermatophyte infections of the skin (except for the scalp and nails). Itraconazole, an azole antifungal, and terbinafine, an allylamine oral antifungal, have excellent activity against dermatophytes and can be used in shorter courses than griseofulvin.

Fluconazole has excellent activity against yeasts and may be the treatment of choice for many forms of mucocutaneous candidiasis.

Itraconazole, fluconazole, and terbinafine can all cause elevation of liver function tests and—though rarely in the dosing regimens used for the treatment of dermatophytosis—clinical hepatitis. Ketoconazole is no longer recommended for the treatment of dermatophytosis (except for tinea versicolor) because of the higher rate of hepatitis when it is used for more than a month.

General Measures & Prevention

Since moist skin favors the growth of fungi, dry the skin carefully after bathing or after perspiring heavily. Talc or other drying powders may be useful. The use of topical corticosteroids for other diseases may be complicated by intercurrent tinea or candidal infection, and topical antifungals are often used in intertriginous areas with corticosteroids to prevent this.

Tinea Corporis or Tinea Circinata (Body Ringworm)

Essentials of Diagnosis

- Ring-shaped lesions with an advancing scaly border and central clearing or scaly patches with a distinct border.
- On exposed skin surfaces or the trunk.
- Microscopic examination of scrapings or culture confirms the diagnosis.

General Considerations

The lesions are often on exposed areas of the body such as the face and arms. A history of exposure to an infected cat may occasionally be obtained, usually indicating *Microsporum* infection. *Trichophyton rubrum* is the most common pathogen, usually representing extension onto the trunk or extremities of tinea cruris, pedis, or manuum.

Clinical Findings

Symptoms and Signs

Itching may be present. In classic lesions, rings of erythema have an advancing scaly border and central clearing (Plates 13 and 14); (see photograph); (see photograph); (see photograph).

Plate 13.

Fig.
Tinea corporis. Typical papulosquamous plaque on the arm in chronic, widespread dermatophytosis. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Laboratory Findings

The diagnosis may be confirmed by KOH preparation or culture.

Differential Diagnosis

Positive fungal studies distinguish tinea corporis from other skin lesions with annular configuration, such as the annular lesions of psoriasis (see photograph), lupus erythematosus, syphilis, granuloma annulare, and pityriasis rosea. Psoriasis has typical lesions on elbows, knees, scalp, and nails. Secondary syphilis is often manifested by characteristic palmar, plantar, and mucous membrane lesions. Tinea corporis rarely has the large number of lesions seen in pityriasis rosea (see photograph). Granuloma annulare lacks scales.

Fig.

Annular psoriasis can mimic tinea corporis. (Courtesy of I Frieden.)

Complications

Complications include extension of the disease down the hair follicles (in which case it becomes much more difficult to cure) and pyoderma.

Prevention

Treat infected household pets (*Microsporum* infections).

Treatment

Local Measures

Tinea corporis responds to most topical antifungals, including miconazole, clotrimazole, butenafine, and terbinafine, which are available over the counter (Table 6–2). Terbinafine and butenafine require shorter courses and lead to the most rapid response. Treatment should be continued for 1–2 weeks after clinical clearing. Betamethasone dipropionate with clotrimazole (Lotrisone) is not recommended. Long-term improper use may result in side effects from the high-potency corticosteroid component, especially in body folds. Cases of tinea that are clinically resistant to this combination but respond to topical antifungals without the topical corticosteroid can occur.

Systemic Measures

Griseofulvin (ultramicrosize), 250–500 mg twice daily, is used. Typically, only 4–6 weeks of therapy are required. Itraconazole as a single week-long pulse of 200 mg daily is also effective in tinea corporis. Terbinafine, 250 mg daily for 1 month, is an alternative.

Prognosis

Body ringworm usually responds promptly to conservative topical therapy or to an oral agent within 4 weeks.

Tinea Cruris (Jock Itch)

Essentials of Diagnosis

- Marked itching in intertriginous areas, usually sparing the scrotum.
- Peripherally spreading, sharply demarcated, centrally clearing erythematous lesions.
- May have associated tinea infection of feet or toenails.
- Laboratory examination with microscope or culture confirms diagnosis.

General Considerations

Tinea cruris lesions are confined to the groin and gluteal cleft. Intractable pruritus ani may occasionally be caused by a tinea infection.

Clinical Findings

Symptoms and Signs

Itching may be severe, or the rash may be asymptomatic. The lesions have sharp margins, cleared centers, and active, spreading scaly peripheries (Plate 15). Follicular pustules are sometimes encountered. The area may be hyperpigmented on resolution.

Plate 15.

Tinea cruris. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

Laboratory Findings

Hyphae can be demonstrated microscopically in KOH preparations (see micrograph). The organism may be cultured.

Differential Diagnosis

Tinea cruris must be distinguished from other lesions involving the intertriginous areas, such as candidiasis, seborrheic dermatitis, intertrigo, psoriasis of body folds ("inverse psoriasis"), and erythrasma. Candidiasis is generally bright red and marked by satellite papules and pustules outside of the main border of the lesion (see photograph). *Candida* typically involves the scrotum. Seborrheic dermatitis also often involves the face, sternum, and axillae. Intertrigo tends to be more red, less scaly, and present in obese individuals in moist body folds with less extension onto the thigh. Inverse psoriasis is characterized by distinct plaques (see photograph). Other areas of typical psoriatic involvement should be checked, and the KOH examination will be negative. Erythrasma is best diagnosed with Wood's (ultraviolet) light—a brilliant coral-red fluorescence is seen (see photograph); (see photograph).

Fig.

Fig.

Erythrasma presenting in the axillary fold. (Courtesy of K Zipperstein.)

Fig.

A diagnostic feature of erythrasma is the coral-red fluorescence observed here in focal distribution under a Wood's light. (Courtesy of K Zipperstein.)

Treatment

General Measures

Drying powder (eg, miconazole nitrate [Zeasorb-AF]) can be dusted into the involved area in patients with excessive perspiration or occlusion of skin due to obesity. Underwear should be loose-fitting.

Local Measures

Any of the preparations listed in Table 6–2 may be used. Terbinafine cream is curative in over 80% of cases after once-daily use for 7 days.

Systemic Measures

Griseofulvin ultramicrosize is reserved for severe cases. Give 250–500 mg orally twice daily for 1–2 weeks. One week of either itraconazole, 200 mg daily, or terbinafine, 250 mg daily, can be effective.

Prognosis

Tinea cruris usually responds promptly to topical or systemic treatment but often recurs.

Tinea Manuum & Tinea Pedis (Dermatophytosis, Tinea of Palms & Soles, "Athlete's Foot")

Essentials of Diagnosis

- Most often presenting with asymptomatic scaling.
- May progress to fissuring or maceration in toe web spaces.
- Common cofactor in lower leg cellulitis
- Itching, burning, and stinging of interdigital web; scaling palms, and soles; vesicles of soles in inflammatory cases.
- The fungus is shown in skin scrapings examined microscopically or by culture of scrapings.

General Considerations

Tinea of the feet is an extremely common acute or chronic dermatosis. Certain individuals appear to be more susceptible than others. Most infections are caused by *Trichophyton* species.

Clinical Findings

Symptoms and Signs

The presenting symptom may be itching, burning, or stinging. Pain may indicate secondary infection with complicating cellulitis. Interdigital tinea pedis is the most common predisposing cause of lower leg cellulitis in healthy individuals. Tinea pedis has several presentations that vary with the location (see photograph). On the sole and heel, tinea may appear as chronic noninflammatory scaling, occasionally with thickening and fissuring. This may extend over the sides of the feet in a "moccasin" distribution. The KOH preparation is usually positive. Tinea pedis often appears as a scaling or fissuring of the toe webs, perhaps with sodden maceration (Plate 16). As the web spaces become more macerated, the KOH preparation and fungal culture are less often positive because bacterial species begin to dominate. Finally, there may also be grouped vesicles distributed anywhere on the soles, generalized exfoliation of the skin of the soles, or nail involvement in the form of discoloration and thickening and crumbling of the nail plate.

Fig.
A: Interdigital tinea pedis: Maceration is prominent. ***B:*** Vesicular tinea pedis: Grouped vesicles on the lateral aspect of the foot at the plantar-glabrous skin junction. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by

The McGraw-Hill Companies, Inc.)

Plate 16.

Tinea pedis in the interdigital space between fourth and fifth digits. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

Laboratory Findings

KOH and culture does not always demonstrate pathogenic fungi from macerated areas.

Differential Diagnosis

Differentiate from other skin conditions involving the same areas, such as interdigital erythrasma (use Wood's light). Psoriasis may be a cause of chronic scaling on the palms or soles and may cause nail changes. Repeated fungal cultures should be negative, and the condition will not respond to antifungal therapy. Contact dermatitis (from shoes) will often involve the dorsal surfaces and will respond to topical or systemic corticosteroids (see photograph). Vesicular lesions should be differentiated from pompholyx (dyshidrosis) and scabies by proper scraping of the roofs of individual vesicles (see photograph); (see photograph). Rarely, gram-negative organisms may cause toe web infections, manifested as an acute erosive flare of interdigital disease. This entity is treated with aluminum salts (see below) and imidazole antifungal agents or ciclopirox.

Fig.

Allergic contact dermatitis due to nickel. A chronic nature is suggested by the scaling and thickened skin. (Courtesy of R Odom.)

Fig.

Dyshidrosis: classic "tapioca" vesicles may be intensely pruritic leading to scaling and fissuring in advanced cases. (Courtesy of S Goldstein.)

Fig.

Typical site for excoriated, vesiculopustular lesions due to scabies. (Courtesy of S Goldstein.)

Prevention

The essential factor in prevention is personal hygiene. Wear open-toed sandals if possible. Use of sandals in community showers and bathing places is often recommended, though the effectiveness of this practice has not been studied. Careful drying between the toes after showering is essential. A hair dryer used on low setting may be used. Socks should be changed frequently, and absorbent nonsynthetic socks are preferred. Apply dusting and drying powders as necessary. The use of powders containing antifungal agents (eg, Zeasorb-AF) or chronic use of antifungal creams may prevent recurrences of tinea pedis.

Treatment

Local Measures

Macerated stage

Treat with aluminum subacetate solution soaks for 20 minutes twice daily. Broad-spectrum antifungal creams and solutions (containing imidazoles or ciclopirox instead of tolnaftate and haloprogin) will help combat diphtheroids and other gram-positive organisms present at this stage and alone may be adequate therapy. If topical imidazoles fail, 1 week of once-daily topical allylamine treatment (terbinafine or butenafine) will often result in clearing.

Dry and scaly stage

Use any of the agents listed in Table 6–2. The addition of urea 10–20% lotion or cream may increase the efficacy of topical treatments in thick ("moccasin") tinea of the soles.

Systemic Measures

Griseofulvin may be used for severe cases or those recalcitrant to topical therapy. If the infection is cleared by systemic therapy, the patient should be encouraged to begin maintenance with topical therapy, since recurrence is common. Itraconazole, 200 mg daily for 2 weeks or 400 mg daily for 1 week, or terbinafine, 250 mg daily for 2–4 weeks, may be used in refractory cases.

Prognosis

For many individuals, tinea pedis is a chronic affliction, temporarily cleared by therapy only to recur.

Nadalo D et al. What is the best way to treat tinea cruris? J Fam Pract. 2006 Mar;55(3):256–8. [PMID: 16428155]

Tinea Versicolor (Pityriasis Versicolor)

Essentials of Diagnosis

- Velvety, tan, or pink macules or white macules that do not tan.
- Fine scales that are not visible but are seen by scraping the lesion.
- Central upper trunk the most frequent site.
- Yeast and short hyphae observed on microscopic examination of scales.

General Considerations

Tinea versicolor is a mild, superficial *Malassezia* infection of the skin (usually of the upper trunk). This yeast is a colonizer of all humans, which accounts for the high recurrence rate after treatment. The eruption is often called to patients' attention by the fact that the involved areas will not tan, and the resulting hypopigmentation may be mistaken for vitiligo. A hyperpigmented form is not uncommon.

Clinical Findings

Symptoms and Signs

Lesions are asymptomatic, but a few patients note itching.

The lesions are velvety, tan, pink, or white macules that vary from 4–5 mm in diameter to large confluent areas (see photograph); (see photograph). The lesions initially do not look scaly, but scales may be readily obtained by scraping the area. Lesions may appear on the trunk, upper arms, neck, and groin.

Fig.

Extensive hypopigmented lesions of tinea versicolor in a black patient. (Courtesy of S Goldstein.)

Laboratory Findings

Large, blunt hyphae and thick-walled budding spores ("spaghetti and meatballs") are seen on KOH (see micrograph). Fungal culture is not useful.

Fig.

Tinea versicolor diagnosed by KOH preparation. Note short hyphal elements and numerous spores not seen in KOH preparations of true dermatophytes. (Courtesy of S Goldstein.)

Differential Diagnosis

Vitiligo usually presents with larger periorificial lesions. Vitiligo (and not tinea versicolor) is characterized by total depigmentation, not just a lessening of pigmentation (see photograph). Vitiligo does not scale. Pink and red-brown lesions on the chest are differentiated from seborrheic dermatitis of the same areas by the KOH preparation (see photograph).

Fig.
Vitiligo: depigmented macules. (Reproduced, with permission, from Bondi EE, Jegasothy BV, Lazarus GS [editors]: *Dermatology: Diagnosis & Treatment*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Treatment & Prognosis

Topical treatments include selenium sulfide lotion, which may be applied from neck to waist daily and left on for 5–15 minutes for 7 days; this treatment is repeated weekly for a month and then monthly for maintenance. Ketoconazole shampoo, 1% or 2%, lathered on the chest and back and left on for 5 minutes may also be used weekly for treatment and to prevent recurrence. Clinicians must stress to the patient that the raised and scaly aspects of the rash are being treated; the alterations in pigmentation may take months to fade or fill in.

Ketoconazole, 200 mg daily orally for 1 week or 400 mg as a single oral dose, with exercise to the point of sweating after ingestion, results in short-term cure of 90% of cases. Patients should be instructed not to shower for 8–12 hours after taking ketoconazole, because it is delivered in sweat to the skin. The single dose may not work in more hot and humid areas, and more protracted therapy carries a small risk of drug-induced hepatitis. Two doses of oral fluconazole, 300 mg, 14 days apart has similar efficacy. Without maintenance therapy, recurrences will occur in over 80% of "cured" cases over the subsequent 2 years. Imidazole creams, solutions, and lotions are quite effective for localized areas but are too expensive for use over large areas such as the chest and back.

Yazdanpanah MJ et al. Comparison between fluconazole and ketoconazole effectivity in the treatment of pityriasis versicolor. Mycoses. 2007 Jul;50(4):311–3. [PMID: 17576325]

Discoid Lupus Erythematosus (Chronic Cutaneous Lupus Erythematosus)

Essentials of Diagnosis

- Localized red plaques, usually on the face.
- Scaling, follicular plugging, atrophy, dyspigmentation, and telangiectasia of involved areas.
- Histology distinctive.
- Photosensitive.

General Considerations

The two most common forms of chronic cutaneous lupus erythematosus (CCLE) are chronic scarring (discoid) lesions (DLE) and erythematous non-scarring red plaques (subacute cutaneous LE) (SCLE). Both occur most frequently in areas exposed to solar irradiation. Permanent hair loss and loss of pigmentation are common sequelae of discoid lesions. Systemic lupus erythematosus (SLE) is discussed in Chapter 19: Musculoskeletal & Immunologic Disorders. Patients with SLE may have DLE or SCLE lesions.

Clinical Findings

Symptoms and Signs

Symptoms are usually mild. The lesions consist of dusky red, well-localized, single or multiple plaques, 5–20 mm in diameter, usually on the head in DLE and the trunk in SCLE. In DLE, the scalp, face, and external ears may be involved (see photograph). In discoid lesions there is atrophy, telangiectasia, depigmentation, and follicular plugging. On the scalp, significant permanent hair loss may occur in lesions of DLE.

Fig.

Lupus erythematosus: photodistribution. (Reproduced, with permission, from Bondi EE, Jegasothy BV, Lazarus GS [editors]: *Dermatology: Diagnosis & Treatment*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Fig.

Discoid lupus erythematosus of the scalp causing scarring, hair loss, and depigmentation. Scaling is seen at the edges of the lesion. (Courtesy of S Goldstein.)

Laboratory Findings

If antinuclear antibody (ANA) is positive in high titer, or when lesions are widespread (not localized to the head), the findings of antibody to double-stranded DNA and hypocomplementemia suggest the diagnosis of SLE. Rare patients with marked photosensitivity and a picture otherwise suggestive of lupus have negative ANA tests but are positive for antibodies against Ro/SSA (SCLE).

Differential Diagnosis

The diagnosis is based on the clinical appearance confirmed by skin biopsy in all cases. In DLE, the scales are dry and "thumbtack-like" and can thus be distinguished from those of seborrheic dermatitis and psoriasis (see photograph); (see photograph). Older lesions that have left depigmented scarring (classically in the concha of the ear) or areas of hair loss will also differentiate lupus from these diseases. Ten percent of patients with SLE have discoid skin lesions, and 5% of patients with discoid lesions have SLE. Medications (hydrochlorothiazide, calcium channel blockers, terbinafine) may induce SCLE with a positive Ro/SSA.

Treatment

General Measures

Protect from sunlight. Use high-SPF (> 50) sunblock with UVB and UVA coverage daily. **Caution:** Do not use any form of radiation therapy. Avoid using drugs that are potentially photosensitizing when possible.

Local Treatment

For limited lesions, the following should be tried before systemic therapy: high-potency corticosteroid creams applied each night and covered with airtight, thin, pliable plastic film (eg, Saran Wrap); or Cordran tape; or ultra-high-potency corticosteroid cream or ointment applied twice daily without occlusion.

Local Infiltration

Triamcinolone acetonide suspension, 2.5–10 mg/mL, may be injected into the lesions once a month.

Systemic Treatment

Antimalarials

Caution: These drugs should be used only when the diagnosis is secure because they have been associated with flares of psoriasis, which may be in the differential diagnosis. They may also cause ocular changes, and ophthalmologic evaluation is required at the onset of therapy and at regular intervals during treatment.

Hydroxychloroquine sulfate

0.2–0.4 g orally daily for several months may be effective and is often used prior to chloroquine. A minimum 3-

month trial is recommended.

Chloroquine sulfate

250 mg daily may be effective in some cases where hydroxychloroquine is not.

Quinacrine (Atabrine)

100 mg daily may be the safest of the antimalarials, since eye damage has not been reported. It colors the skin yellow and is therefore not acceptable to some patients. It may be added to the other antimalarials for incomplete responses.

Isotretinoin

Isotretinoin, 1 mg/kg/d, is effective in CCLE or SCLE. Recurrences are prompt and predictable on discontinuation of therapy.

Thalidomide

Thalidomide is effective in refractory cases in doses of up to 300 mg daily. Monitor for neuropathy.

Both isotretinoin and thalidomide are teratogens and should be used with appropriate contraception and monitoring in women of childbearing age.

Prognosis

The disease is persistent but not life-endangering unless systemic lupus is present. Treatment with antimalarials is effective in perhaps 60% of cases. Although the only morbidity may be cosmetic, this can be of overwhelming significance in more darkly pigmented patients with widespread disease. Scarring alopecia can be prevented or lessened with close attention and aggressive therapy.

Lee HJ et al. Cutaneous lupus erythematosus: understanding of clinical features, genetic basis, and pathobiology of disease guides therapeutic strategies. Autoimmunity. 2006 Sep;39(6):433–44. [PMID: 17060022]

Cutaneous T Cell Lymphoma (Mycosis Fungoides)

Essentials of Diagnosis

- Localized or generalized erythematous scaling patches and plaques.
- Pruritus.
- Lymphadenopathy.
- Distinctive histology.

General Considerations

Mycosis fungoides is a cutaneous T cell lymphoma that begins on the skin and may involve only the skin for years or decades. Certain medications (including selective serotonin reuptake inhibitors) may produce eruptions clinically and histologically identical to those of mycosis fungoides.

Clinical Findings

Symptoms and Signs

Localized or generalized erythematous patches or plaques are present usually on the trunk. Plaques are almost always over 5 cm in diameter. Pruritus is a frequent complaint. The lesions often begin as nondescript or nondiagnostic patches, and it is not unusual for the patient to have skin lesions for more than a decade before the diagnosis can be confirmed. In more advanced cases, tumors appear. Lymphadenopathy may occur locally or widely. Lymph node enlargement may be due to benign expansion of the node (dermatopathic lymphadenopathy) or by specific involvement with mycosis fungoides.

Laboratory Findings

The skin biopsy remains the basis of diagnosis, though at times numerous biopsies are required before the diagnosis can be confirmed. In more advanced disease, circulating atypical cells (Sézary cells) can be detected in the blood by sensitive methods. Eosinophilia may be present.

Differential Diagnosis

Mycosis fungoides may be confused with psoriasis, a drug eruption, an eczematous dermatitis, Hansen disease (leprosy), or tinea corporis. Histologic examination can distinguish these conditions.

Treatment

The treatment of mycosis fungoides is complex. Early and aggressive treatment has not proved to cure or prevent progression of the disease. Skin-directed therapies including topical corticosteroids, topical mechlorethamine, bexarotene gel, and UV phototherapy, are used initially. If the disease progresses, PUVA plus retinoids, PUVA plus interferon, extracorporeal photophoresis, bexarotene, alpha-interferon with or without retinoids, interleukin 12, denileukin, and total skin electron beam are used if the condition progresses. If these low toxicity systemic and biologic agents fail, standard chemotherapies, starting with single agents, are used.

Prognosis

Mycosis fungoides is usually slowly progressive (over decades). Prognosis is better in patients with patch or plaque stage disease and worse in patients with erythroderma, tumors, and lymphadenopathy. Survival is not reduced in patients with limited patch disease. Elderly patients with patch and plaque stage disease commonly die of other causes. Overly aggressive treatment may lead to complications and premature demise.

Blood. 2007 Sep 15;110(6):1713–22. [PMID: 17540844]

Exfoliative Dermatitis (Exfoliative Erythroderma)

Essentials of Diagnosis

- Scaling and erythema over most of the body.
- Itching, malaise, fever, chills, weight loss.

General Considerations

Erythroderma describes generalized redness and scaling of the skin of more than 30% BSA. A preexisting dermatosis is the cause of exfoliative dermatitis in two-thirds of cases, including psoriasis, atopic dermatitis, contact dermatitis, pityriasis rubra pilaris, and seborrheic dermatitis. Reactions to topical or systemic drugs account for perhaps 20–40% of cases and cancer (cutaneous T cell lymphoma, Sézary syndrome) for 10–20%. Causation of the remainder is indeterminable. At the time of acute presentation, without a clear-cut prior history of skin disease or drug exposure, it may be impossible to make a specific diagnosis of the underlying condition, and diagnosis may require observation.

Clinical Findings

Symptoms and Signs

Symptoms may include itching, weakness, malaise, fever, and weight loss. Chills are prominent. Redness and scaling is widespread. Loss of hair and nails can occur. Generalized lymphadenopathy may be due to lymphoma or leukemia or may be reactive. The mucosae are spared.

Laboratory Findings

A skin biopsy is required and may show changes of a specific inflammatory dermatitis or cutaneous T cell lymphoma or leukemia. Peripheral leukocytes may show clonal rearrangements of the T cell receptor in Sézary syndrome.

Differential Diagnosis

It may be impossible to identify the cause of exfoliative erythroderma early in the course of the disease, so careful follow-up is necessary.

Complications

Debility (protein loss) and dehydration may develop in patients with generalized inflammatory exfoliative erythroderma, or sepsis may occur.

Treatment

Topical Therapy

Home treatment is with cool to tepid baths and application of mid-potency corticosteroids under wet dressings or with the use of an occlusive plastic suit. If the exfoliative erythroderma becomes chronic and is not manageable in an outpatient setting, hospitalize the patient. Keep the room at a constant warm temperature and provide the same topical treatment as for an outpatient.

Specific Measures

Stop all drugs, if possible. Systemic corticosteroids may provide spectacular improvement in severe or fulminant exfoliative dermatitis, but long-term therapy should be avoided (see Chapter 26: Endocrine Disorders). In addition, systemic corticosteroids must be used with caution because some patients with erythroderma have psoriasis and could develop pustular psoriasis. For cases of psoriatic erythroderma and pityriasis rubra pilaris, either acitretin or methotrexate may be indicated. Erythroderma secondary to lymphoma or leukemia requires specific topical or systemic chemotherapy. Suitable antibiotic drugs with coverage for *Staphylococcus* should be given when there is evidence of bacterial infection.

Prognosis

Most patients recover completely or improve greatly over time but may require long-term therapy. Deaths are rare in the absence of cutaneous T cell lymphoma. A minority of patients will suffer from undiminished erythroderma for indefinite periods.

Jaffer AN et al. Exfoliative dermatitis. Erythroderma can be a sign of a significant underlying disorder. Postgrad Med. 2005 Jan;117(1):49–51. [PMID: 15672891]

Miscellaneous Scaling Dermatoses

Isolated scaly patches may represent actinic (solar) keratoses, nonpigmented keratoses or Bowen or Paget disease.

Actinic Keratoses

Actinic keratoses are small (0.2–0.6 cm) macules or papules—flesh-colored, pink, or slightly hyperpigmented—that feel like sandpaper and are tender when the finger is drawn over them. They occur on sun-exposed parts of the body in persons of fair complexion. Actinic keratoses are considered premalignant, but only 1:1000 lesions per year progress to become squamous cell carcinomas.

Application of liquid nitrogen is a rapid and effective method of eradication. The lesions crust and disappear in 10–14 days. An alternative treatment is the use of fluorouracil cream. This agent may be rubbed into the lesions morning and night until they become first red and sore and then crusted and eroded (usually 2–3 weeks). Carac (0.5%fluorouracil) may be used once daily for a longer period (6 weeks to several months). Keratoses may clear with less irritation. Imiquimod 5% cream applied two to three times weekly for 3–6 weeks is the more costly alternative to topical fluorouracil (5FU). Any lesions that persist should be evaluated for possible biopsy.

McIntyre WJ et al. Treatment options for actinic keratoses. Am Fam Physician. 2007 Sep 1;76(5):667–71. [PMID: 17894135]

Bowen Disease & Paget Disease

Bowen disease (intraepidermal squamous cell carcinoma) occurs either on sun-exposed or sun-protected skin. The lesion is usually a small (0.5–3 cm), well-demarcated, slightly raised, pink to red, scaly plaque and may resemble psoriasis or a large actinic keratosis (see photograph). These lesions may progress to invasive squamous cell carcinoma. Excision or other definitive treatment is indicated.

Fig.

This isolated, scaly patch on a patient's arm turned out to be Bowen's disease (intraepidermal squamous cell carcinoma) on biopsy. (Courtesy of S Goldstein.)

Extramammary Paget disease, a manifestation of intraepidermal carcinoma or underlying genitourinary or gastrointestinal cancer, resembles chronic eczema and usually involves apocrine areas such as the genitalia. Mammary Paget disease of the nipple, a unilateral or rarely bilateral red scaling plaque that may ooze, is associated with an underlying intraductal mammary carcinoma (Plate 17).

Plate 17.

Kanitakis J. Mammary and extramammary Paget's disease. J Eur Acad Dermatol Venereol. 2007 May;21(5):581–90. [PMID: 17447970]

Intertrigo

Intertrigo is caused by the macerating effect of heat, moisture, and friction. It is especially likely to occur in obese persons and in humid climates. The symptoms are itching, stinging, and burning. The body folds develop fissures, erythema, and sodden epidermis, with superficial denudation (see photograph). Candidiasis may complicate intertrigo (see photograph); (see photograph). "Inverse psoriasis" (see photograph), seborrheic dermatitis, tinea cruris, erythrasma (see photograph), and candidiasis must be ruled out.

Maintain hygiene in the area, and keep it dry. Compresses may be useful acutely. Hydrocortisone 1% cream plus an imidazole or nystatin cream is effective. Recurrences are common.

Fig.

Candidal intertrigo. (Reproduced, with permission, from Bondi EE, Jegasothy BV, Lazarus GS [editors]: *Dermatology: Diagnosis & Treatment*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Herpes Simplex (Cold or Fever Sore; Genital Herpes)

Essentials of Diagnosis

- Recurrent small grouped vesicles on an erythematous base, especially in the orolabial and genital areas.
- May follow minor infections, trauma, stress, or sun exposure; regional lymph nodes may be swollen and tender.
- Viral cultures and direct fluorescent antibody tests are positive.

General Considerations

Over 85% of adults have serologic evidence of herpes simplex type 1 (HSV-1) infections, most often acquired asymptomatically in childhood. Occasionally, primary infections may be manifested as severe gingivostomatitis. Thereafter, the patient may have recurrent self-limited attacks, provoked by sun exposure, orofacial surgery, fever, or a viral infection.

About 25% of the United States population has serologic evidence of infection with herpes simplex type 2 (HSV-2). HSV-2 causes lesions whose morphology and natural history are similar to those caused by HSV-1 on the genitalia of both sexes. The infection is acquired by sexual contact. In monogamous heterosexual couples where one partner has HSV-2 infection, seroconversion of the noninfected partner occurs in 10% over a 1-year period. Up to 70% of such infections appeared to be transmitted during periods of asymptomatic shedding. Genital herpes may also be due to HSV-1.

Clinical Findings

Symptoms and Signs

The principal symptoms are burning and stinging. Neuralgia may precede or accompany attacks. The lesions consist of small, grouped vesicles that can occur anywhere but which most often occur on the vermilion border of the lips, the penile shaft, the labia, the perianal skin, and the buttocks (Plates 18 and 19); (see photograph); (see photograph). Any erosion in the genital region can be due to HSV-2 (or HSV-1). Regional lymph nodes may be swollen and tender. The lesions usually crust and heal in 1 week. Herpes simplex is the most common cause of painful genital ulcerations in patients with HIV infection.

Laboratory Findings

Lesions of herpes simplex must be distinguished from chancroid, syphilis, pyoderma, or trauma. Direct immunofluorescent antibody slide tests offer rapid, sensitive diagnosis. Viral culture may also be helpful. Herpes serology is not used in the diagnosis of an acute genital ulcer. However, specific HSV 2 serology by Western blot assay or enzyme-linked immunosorbent assay (ELISA) can determine who is HSV-infected and potentially infectious. Such testing is very useful in couples in which only one partner reports a history of genital herpes.

Complications

Complications include pyoderma, eczema herpeticum, herpetic whitlow (see photograph), herpes gladiatorum (epidemic herpes in wrestlers transmitted by contact), proctitis, esophagitis, neonatal infection, keratitis, and encephalitis.

Fig.

Prevention

Sunscreens are useful adjuncts in preventing sun-induced recurrences. Prophylactic use of oral acyclovir may prevent recurrences. Acyclovir should be started at a dosage of 200 mg four times daily beginning 24 hours prior to ultraviolet light exposure, dental surgery, or orolabial cosmetic surgery. Comparable doses are 500 mg twice daily for valacyclovir and 250 mg twice daily for famciclovir.

Treatment

Systemic Therapy

Three systemic agents are available for the treatment of herpes infections: acyclovir, its valine analog valacyclovir, and famciclovir. All three agents are very effective and, when used properly, virtually nontoxic. Only acyclovir is available for intravenous administration. In the immunocompetent, with the exception of severe orolabial herpes, only genital disease is treated. For first clinical episodes of herpes simplex, the dosage of acyclovir is 200 mg orally five times daily (or 800 mg three times daily); of valacyclovir, 1000 mg twice daily; and of famciclovir, 250 mg three times daily. The duration of treatment is from 7 to 10 days depending on the severity of the outbreak. Most cases of recurrent herpes are mild and do not require therapy. In addition, pharmacotherapy of recurrent HSV is of limited benefit, with studies finding a reduction in the average outbreak by only 12–24 hours. To be effective, the treatment must be initiated by the patient at the first sign of recurrence. If treatment is desired, recurrent genital herpes outbreaks may be treated with 3 days of valacyclovir, 500 mg twice daily; or with 5 days of acyclovir, 200 mg five times a day, or famciclovir, 125 mg twice daily. Valacyclovir, 2 g twice daily for 1 day, or famciclovir, 1 g once or twice in 1 day, are equally effective short-course alternatives, and can abort impending recurrences of both orolabial or genital herpes. The addition of a potent topical corticosteroid three times daily reduces the duration, size, and pain of orolabial herpes treated with an oral antiviral agent.

In patients with frequent or severe recurrences, suppressive therapy is most effective in controlling disease. Suppressive treatment will reduce outbreaks by 85% and reduces viral shedding by more than 90%. This results in about a 50% reduced risk of transmission. The recommended suppressive doses, taken continuously, are acyclovir, 400 mg twice daily; valacyclovir, 500 mg once daily; or famciclovir, 125–250 mg twice daily. Long-term suppression appears very safe, and after 5–7 years a substantial proportion of patients can discontinue treatment. The use of condoms and patient education have proved effective in reducing genital herpes transmission in some studies and in others have not been beneficial. No single or combination intervention absolutely prevents transmission.

Local Measures

In general, topical therapy is not effective. It is strongly urged that 5%acyclovir ointment, if used at all, be limited to the restricted indications for which it has been approved, ie, initial herpes genitalis and mucocutaneous herpes simplex infections in immunocompromised patients. Penciclovir cream, to be applied at the first symptom every 2 hours while awake for 4 days for recurrent orolabial herpes, reduces the average attack duration from 5 days to 4.5 days.

Prognosis

Aside from the complications described above, recurrent attacks last several days, and patients recover without sequelae.

Herpes Zoster (Shingles)

Essentials of Diagnosis

- Pain along the course of a nerve followed by grouped vesicular lesions.
- Involvement is unilateral; some lesions (< 20) may occur outside the affected dermatome.
- Lesions are usually on face or trunk.
- Direct fluorescent antibody positive, especially in vesicular lesions.

General Considerations

Herpes zoster is an acute vesicular eruption due to the varicella-zoster virus. It usually occurs in adults. With rare exceptions, patients suffer only one attack. Dermatomal herpes zoster does not imply the presence of a visceral malignancy. Generalized disease, however, raises the suspicion of an associated immunosuppressive disorder such as Hodgkin disease or HIV infection. HIV-infected patients are 20 times more likely to develop zoster, often before other clinical findings of HIV disease are present. A history of HIV risk factors and HIV testing when appropriate should be considered, especially in patients with zoster who are younger than 55 years.

Clinical Findings

Pain usually precedes the eruption by 48 hours or more and may persist and actually increase in intensity after the lesions have disappeared. The lesions consist of grouped, tense, deep-seated vesicles distributed unilaterally along a dermatome (Plate 20); (see photograph). The most common distributions are on the trunk or face. Up to 20 lesions may be found outside the affected dermatomes. Regional lymph glands may be tender and swollen.

Plate 20.

Herpes zoster. (Used, with permission, from Berger TG, Dept. Dermatology, UCSF.)

Fig.

Clusters of umbilicated herpes zoster vesicles erupt in linear, dermatomal patterns. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Differential Diagnosis

Since poison oak and poison ivy dermatitis can occur unilaterally, they must be differentiated at times from herpes zoster (see photograph). Allergic contact dermatitis is pruritic; zoster is painful. One must differentiate herpes zoster from lesions of herpes simplex, which occasionally occurs in a dermatomal distribution. Doses of antivirals appropriate for zoster should be used in the absence of a clear diagnosis. Facial zoster may simulate erysipelas initially, but zoster is unilateral and shows vesicles after 24–48 hours. The pain of preeruptive herpes zoster may lead the clinician to diagnose migraine, myocardial infarction, acute abdomen, herniated disc, etc, depending on the dermatome involved.

Complications

Sacral zoster may be associated with bladder and bowel dysfunction. Persistent neuralgia, anesthesia or scarring of the affected area, facial or other nerve paralysis, and encephalitis may occur. Postherpetic neuralgia is most common after involvement of the trigeminal region, and in patients over the age of 55. Early (within 72 hours after onset) and aggressive antiviral treatment of herpes zoster reduces the severity and duration of postherpetic neuralgia. Zoster ophthalmicus (V_1) can result in visual impairment.

Prevention

An effective live herpes zoster vaccine (Zostavax) is available to prevent both herpes zoster and postherpetic neuralgia. It should be considered in persons aged 60 and older.

Treatment

General Measures

Immunocompetent host

Since early treatment of zoster reduces postherpetic neuralgia, those with a risk of developing this complication should be treated, ie, those over age 50 and those with nontruncal eruption. In addition, younger patients with acute moderate to severe pain or rash may benefit from effective antiviral therapy. Treatment can be given with oral acyclovir, 800 mg five times daily; famciclovir, 500 mg three times daily; or valacyclovir, 1 g three times daily—all for 7 days (see Chapter e1: Anti-infective Chemotherapeutic & Antibiotic Agents). For reasons of increased bioavailability and ease of dosing schedule, the preferred agents are those given three times daily. Patients should maintain good hydration. The dose of antiviral should be adjusted for kidney function as recommended. Nerve blocks may be used in the management of initial severe pain. Ophthalmologic consultation is vital for involvement of the first branch of the trigeminal nerve. Systemic corticosteroids are effective in reducing acute pain, improving quality of life, and returning patients to normal activities much more quickly. They do not increase the risk of dissemination in immunocompetent hosts. If not contraindicated, a tapering 3-week course of prednisone, starting at 60 mg/d, should be considered for its adjunctive benefit in immunocompetent patients. Oral corticosteroids do not reduce the prevalence, severity, or duration of postherpetic neuralgia beyond that achieved by effective antiviral therapy.

Immunocompromised host

Given the safety and efficacy of currently available antivirals, most immunocompromised patients with herpes zoster are candidates for antiviral therapy. The dosage schedule is as listed above, but treatment should be continued until the lesions have completely crusted and are healed or almost healed (up to 2 weeks). Because corticosteroids increase the risk of dissemination in immunosuppressed patients, they should not be used in these patients. Progression of disease may necessitate intravenous therapy with acyclovir, 10 mg/kg intravenously, three times daily. After 3–4 days, oral therapy may be substituted if there has been a good response to intravenous therapy. Adverse effects include decreased kidney function from crystallization, nausea and vomiting, and abdominal pain.

Foscarnet, administered in a dosage of 40 mg/kg two or three times daily intravenously, is indicated for treatment of acyclovir-resistant varicella-zoster virus infections.

Local Measures

Calamine or starch shake lotions may be of some help.

Postherpetic Neuralgia Therapy

The most effective treatment is prevention with vaccination of those at risk for developing zoster and early and aggressive antiviral therapy once zoster has occurred. Once established, postherpetic neuralgia may be treated with capsaicin ointment, 0.025–0.075%, or lidocaine (Lidoderm) topical patches. Chronic postherpetic neuralgia may be relieved by regional blocks (stellate ganglion, epidural, local infiltration, or peripheral nerve), with or without corticosteroids added to the injections. Amitriptyline, 25–75 mg as a single nightly dose, is the first-line oral therapy beyond simple analgesics. Gabapentin, up to 3600 mg daily (starting at 300 mg three times daily), may be added for additional pain relief. Referral to a pain management clinic should be considered in moderate to severe cases and in those failing the above treatments.

Prognosis

The eruption persists 2–3 weeks and usually does not recur. Motor involvement in 2–3% of patients may lead to temporary palsy.

Variola (Smallpox) & Vaccinia

Essentials of Diagnosis

- Prodromal high fever.
- Eruption progressing from papules to vesicles to pustules, then crusts.
- All lesions in the same stage.
- Face and distal extremities (including palms and soles) favored.

General Considerations

Concern for the use of smallpox virus as a bioterrorist weapon has led to the reintroduction of vaccination in some segments of the population (first responders and the military).

Clinical Findings

The incubation period for variola averages 12 days (7–17 days). The prodrome begins with abrupt onset of high fever, severe headaches, and backaches. At this stage, the infected person appears quite ill. The infectious phase begins with the appearance of an enanthem, followed in 1–2 days by a skin eruption. The lesions begin as macules, progressing to papules, then pustules, and finally crusts over 14–18 days. The face and distal extremities are favored. The face is affected first, followed by the upper extremities, then the lower extremities and trunk, completely evolving over 1 week. Lesions are relatively monomorphous, especially in each anatomic region.

Inoculation with vaccinia produces a papular lesion on day 2–3 that progresses to an umbilicated papule by day 4 and a pustular lesion by the end of the first week. The lesion then collapses centrally, and crusts. The crust eventually detaches up to a month after the inoculation. Persons with eczema should not be immunized as they may suffer widespread vaccinia (eczema vaccinatum) whose lesions might resemble those of smallpox. Vaccinia is moderately contagious, and patients with atopic dermatitis and Darier disease may acquire severe generalized disease by exposure to a recently vaccinated person. Generalized vaccinia may be fatal. Prior vaccination does not prevent generalized vaccinia, but previously vaccinated individuals have milder disease. Progressive vaccinia (vaccinia gangrenosum)—progression of the primary inoculation site to a large ulceration—occurs in persons with systemic immune deficiency. It can have a fatal outcome.

Differential Diagnosis

Smallpox and vaccinia are to be distinguished from generalized varicella zoster virus infection or generalized herpes simplex. The latter two viral infections are not associated with a severe febrile prodrome. Lesions are at various stages at each anatomic site. Varicella usually appears in waves or crops. Multiple palm and sole lesions are common in variola and uncommon in generalized varicella-zoster and herpes simplex infection.

Direct fluorescent antibody testing for HSV and varicella zoster virus are the first-line diagnostic tests to differentiate varicella zoster virus, HSV, vaccinia, and variola. Until the diagnosis is confirmed, strict isolation of the patient is indicated. Similar fluorescent testing for variola can be performed in special laboratories.

Treatment

There is no specific and proven antiviral therapy for vaccinia or variola. Vaccinia immune globulin is used to treat eczema vaccinatum and progressive vaccinia. Cidofovir may have some activity against these poxviruses.

Moore ZS et al. Smallpox. Lancet. 2006 Feb 4;367(9508):425–35. [PMID: 16458769]

Pompholyx; Vesiculobullous Hand Eczema (Formerly known as Dyshidrosis, Dyshidrotic Eczema)

Essentials of Diagnosis

- "Tapioca" vesicles of 1–2 mm on the palms, soles, and sides of fingers, associated with pruritus.
- Vesicles may coalesce to form multiloculated blisters.
- Scaling and fissuring may follow drying of the blisters.
- Appearance in the third decade, with lifelong recurrences.

General Considerations

This is an extremely common form of hand dermatitis, preferably called pompholyx (Gr "bubble") or vesiculobullous dermatitis of the palms and soles. Patients often have an atopic background and report flares with stress. Patients with widespread dermatitis due to any cause may develop pompholyx-like eruptions as a part of an autoeczematization response.

Clinical Findings

Small clear vesicles stud the skin at the sides of the fingers and on the palms or soles (Plate 21); (see photograph). They look like the grains in tapioca. They may be associated with intense itching. Later, the vesicles dry and the area becomes scaly and fissured.

Plate 21.
Pompholyx (acute vesiculobullous hand eczema). (Used, with permission, from Berger TG, Dept. Dermatology, UCSF.)

Differential Diagnosis

Unroofing the vesicles and examining the blister roof with a KOH preparation will reveal hyphae in cases of bullous tinea. Patients with inflammatory tinea pedis may have a vesicular dermatophytid of the palms. Always examine the feet of a patient with a hand eruption. Nonsteroidal anti-inflammatory drugs (NSAIDs) may produce an eruption very similar to that of dyshidrosis on the hands.

Prevention

There is no known way to prevent attacks.

Treatment

Topical and systemic corticosteroids help some patients dramatically. Since this is a chronic problem, systemic corticosteroids are generally not appropriate therapy. A high-potency topical corticosteroid used early in the attack may help abort the flare and ameliorate pruritus. Topical corticosteroids are also important in treating the scaling and fissuring that are seen after the vesicular phase. It is essential that patients avoid anything that irritates the skin; they should wear cotton gloves inside vinyl gloves when doing dishes or other wet chores, use long-handled brushes instead of sponges, and use a hand cream after washing the hands. Patients respond to PUVA therapy and injection of botulinum toxin into the palms as for hyperhidrosis.

Prognosis

For most patients, the disease is an inconvenience. For some, vesiculobullous hand eczema can be incapacitating.

Lofgren SM et al. Dyshidrosis: epidemiology, clinical characteristics, and therapy. Dermatitis. 2006 Dec;17(4):165–81. [PMID: 17150166]

Porphyria Cutanea Tarda

Essentials of Diagnosis

- Noninflammatory blisters on sun-exposed sites, especially the dorsal surfaces of the hands.
- Hypertrichosis, skin fragility.
- Associated liver disease.
- Elevated urine porphyrins.

General Considerations

Porphyria cutanea tarda is the most common type of porphyria. Cases are sporadic or hereditary. The disease is associated with ingestion of certain medications (eg, estrogens), and liver disease from alcoholism or hepatitis C. In patients with liver disease, hemosiderosis is often present.

Clinical Findings

Symptoms and Signs

Patients complain of painless blistering and fragility of the skin of the dorsal surfaces of the hands (Plate 22); (see photograph). Facial hypertrichosis and hyperpigmentation are common.

Plate 22.

Porphyria cutanea tarda. (Courtesy of Lewis Rose, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

Fig.

Dorsum of the hands of a patient with porphyria cutanea tarda, demonstrating crusting, scarring, and depigmentation due to sunlight-induced fragility of the skin. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Laboratory Findings

Urinary uroporphyrins are elevated twofold to fivefold above coproporphyrins. Patients may also have abnormal liver function tests, evidence of hepatitis C infection, increased liver iron stores, and hemochromatosis gene mutations. Multiple triggering factors are often discovered.

Differential Diagnosis

Skin lesions identical to those of porphyria cutanea tarda may be seen in patients who receive maintenance dialysis and in those who take certain medications (tetracyclines and NSAIDs, especially naproxen, and voriconazole). In this so-called pseudoporphyria, the biopsy results are identical to those associated with porphyria cutanea tarda, but urine porphyrins are normal.

Prevention

Although the lesions are triggered by sun exposure, the wavelength of light triggering the lesions is beyond that absorbed by sunscreens, which for that reason are ineffective. Barrier sun protection with clothing is required.

Treatment

Stopping all triggering medications and substantially reducing or stopping alcohol consumption may alone lead to improvement. Phlebotomy without oral iron supplementation at a rate of 1 unit every 2–4 weeks will gradually lead to improvement. Very low dose antimalarials (as low as 200 mg of hydroxychloroquine twice weekly), alone or in combination with phlebotomy, will increase the excretion of porphyrins, improving the skin disease. Treatment is continued until the patient is asymptomatic. Urine porphyrins may be monitored.

Prognosis

Most patients improve with treatment. Sclerodermoid skin lesions may develop on the trunk, scalp, and face.

Sassa S. Modern diagnosis and management of the porphyrias. Br J Haematol. 2006 Nov;135(3):281–92. [PMID: 16956347]

Dermatitis Herpetiformis

Dermatitis herpetiformis is an uncommon disease manifested by pruritic papules, vesicles, and papulovesicles mainly on the elbows, knees, buttocks, posterior neck, and scalp (see photograph); (see photograph). It appears to have its highest prevalence in Scandinavia and is associated with HLA antigens -B8, -DR3, and -DQ2. The diagnosis is made by light microscopy, which demonstrates neutrophils at the dermal papillary tips. Direct immunofluorescence studies show granular deposits of IgA in the dermal papillae. Circulating antibodies to tissue transglutaminase are present in 90% of cases. NSAIDs may cause a flare. Patients have gluten-sensitive enteropathy, but for the great majority it is subclinical. However, ingestion of gluten is the cause of the disease, and strict long-term avoidance of dietary gluten has been shown to decrease the dose of dapsone (usually 100–200 mg/d) required to control the disease and may even eliminate the need for treatment. Patients with dermatitis herpetiformis are at increased risk for development of gastrointestinal lymphoma, and this risk is reduced by a gluten-free diet.

Zone JJ. Skin manifestations of celiac disease. Gastroenterology. 2005 Apr;128(4 Suppl 1):S87–91. [PMID: 15825132]

Impetigo

Essentials of Diagnosis

- Superficial blisters filled with purulent material that rupture easily.
- Crusted superficial erosions.
- Positive Gram stain and bacterial culture.

General Considerations

Impetigo is a contagious and autoinoculable infection of the skin caused by staphylococci or streptococci.

Clinical Findings

Symptoms and Signs

The lesions consist of macules, vesicles, bullae, pustules, and honey-colored gummy crusts that when removed leave denuded red areas (Plate 23). The face and other exposed parts are most often involved. **Ecthyma** is a deeper form of impetigo caused by staphylococci or streptococci, with ulceration and scarring (see photograph). It occurs frequently on the extremities.

Plate 23.
Bullous impetigo. (Used, with permission, from Berger TG, Dept. Dermatology, UCSF.)

Fig.
Echthyma, shown here, represents a deeper form of impetigo caused by *Staphylococcus aureus* or streptococci. (Courtesy of S Goldstein.)

Laboratory Findings

Gram stain and culture confirm the diagnosis. In temperate climates, most cases are associated with *S aureus* infection. *Streptococcus* species are more common in tropical infections. Community-associated methicillin-resistant *S aureus* (CA-MRSA) can be isolated from lesions of impetigo and ecthyma.

Differential Diagnosis

The main differential diagnoses are acute allergic contact dermatitis (see photograph) and herpes simplex. Contact dermatitis may be suggested by the history or by linear distribution of the lesions, and culture should be negative for staphylococci and streptococci. Herpes simplex infection usually presents with grouped vesicles or discrete erosions and may be associated with a history of recurrences. Viral cultures are positive.

Fig.

Poison Ivy: fine vesicles in a linear pattern. (Reproduced, with permission, from Bondi EE, Jegasothy BV, Lazarus GS [editors]: *Dermatology: Diagnosis & Treatment*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Treatment

Soaks and scrubbing can be beneficial, especially in unroofing lakes of pus under thick crusts. Topical agents such as bacitracin, mupirocin, or retapamulin can be attempted for infections limited to small areas. Mupirocin and retapamulin are more expensive than systemic treatments. In most cases, systemic antibiotics are indicated. Cephalexin, 250 mg four times daily, is usually effective. Doxycycline, 100 mg twice daily, is a reasonable alternative. CA-MRSA may cause impetigo, and initial coverage for MRSA could include doxycycline, clindamycin, or trimethoprim-sulfamethoxazole (TMP-SMZ). About 50% of CA-MRSA cases are quinolone resistant. Recurrent impetigo is associated with nasal carriage of *S aureus*, treated with rifampin, 600 mg daily. Intranasal mupirocin ointment twice daily for 5 days clears the carriage of 40% of MRSA strains. Bleach baths ($^1/_2$ to 1 cup per 20 liters of bathwater for 15 minutes 3-5 times weekly) for all family members, and the use of dilute household bleach to clean showers and other bath surfaces may help reduce the spread. Individuals should not share towels if there is a case of impetigo in the household.

Cole C et al. Diagnosis and treatment of impetigo. Am Fam Physician. 2007 Mar 15;75(6):859–64. [PMID: 17390597]

Allergic Contact Dermatitis

Essentials of Diagnosis

- Erythema and edema, with pruritus, often followed by vesicles and bullae in an area of contact with a suspected agent.
- Later, weeping, crusting, or secondary infection.
- A history of previous reaction to suspected contactant.

- Patch test with agent positive.

General Considerations

Contact dermatitis is an acute or chronic dermatitis that results from direct skin contact with chemicals or allergens. Eighty percent of cases are due to excessive exposure to or additive effects of primary or universal irritants (eg, soaps, detergents, organic solvents) and are called irritant contact dermatitis. This appears red and scaly but not vesicular. The most common causes of allergic contact dermatitis are poison ivy or poison oak; topically applied antimicrobials (especially bacitracin and neomycin), anesthetics (benzocaine); hair-care products; preservatives; jewelry (nickel); rubber; vitamin E; essential oils; propolis (from bees); and adhesive tape. Occupational exposure is an important cause of allergic contact dermatitis. Weeping and crusting are typically due to allergic and not irritant dermatitis.

Clinical Findings

Symptoms and Signs

In allergic contact dermatitis, the acute phase is characterized by tiny vesicles and weepy and crusted lesions, whereas resolving or chronic contact dermatitis presents with scaling, erythema, and possibly thickened skin (Plate 24); (see photograph); (see photograph). Itching, burning, and stinging may be severe. The lesions, distributed on exposed parts or in bizarre asymmetric patterns, consist of erythematous macules, papules, and vesicles. The affected area is often hot and swollen, with exudation and crusting, simulating—and at times complicated by—infection. The pattern of the eruption may be diagnostic (eg, typical linear streaked vesicles on the extremities in poison oak or ivy dermatitis) (see photograph). The location will often suggest the cause: Scalp involvement suggests hair dyes or shampoos; face involvement, creams, cosmetics, soaps, shaving materials, nail polish; and neck involvement, jewelry, hair dyes.

Plate 24.

Contact dermatitis. (Used, with permission, from Berger TG, Dept. Dermatology, UCSF.)

Laboratory Findings

Gram stain and culture will rule out impetigo or secondary infection (impetiginization). If itching is generalized, then scabies should be considered. After the episode has cleared, patch testing may be useful if the triggering allergen is not known.

Differential Diagnosis

Asymmetric distribution, blotchy erythema around the face, linear lesions, and a history of exposure help distinguish acute contact dermatitis from other skin lesions. The most commonly mistaken diagnosis is impetigo (see photograph). Chronic allergic contact dermatitis must be differentiated from scabies (see photograph), atopic dermatitis (see photograph), pompholyx (see photograph), and other eczemas.

Prevention

Prompt and thorough removal of the causative oil by washing with liquid dishwashing soap (eg, Dial Ultra) may be effective if done within 30 minutes after exposure to poison oak or ivy. The three most effective over-the-counter barrier creams which are applied prior to exposure and prevent/reduce the severity of the dermatitis are Stokogard, Hollister Moisture Barrier, and Hydropel.

The mainstay of prevention is identification of the agent causing the dermatitis and avoidance of exposure or use of protective clothing and gloves. In industry-related cases, prevention may be accomplished by moving or retraining the worker.

Treatment

Overview

While local measures are important, severe or widespread involvement is difficult to manage without systemic corticosteroids because even the highest-potency topical corticosteroids seem not to work well on vesicular and weepy lesions. Localized involvement (except on the face) can often be managed solely with topical agents. Irritant contact dermatitis is treated by protection from the irritant and use of topical corticosteroids as for atopic dermatitis (described above). The treatment of allergic contact dermatitis is detailed below.

Local Measures

Acute weeping dermatitis

Compresses are most often used. It is unwise to scrub lesions with soap and water. Calamine lotion may be used between wet dressings, especially for involvement of intertriginous areas or when oozing is not marked. Lesions on the extremities may be bandaged with wet dressings for 30–60 minutes several times a day. High potency topical corticosteroids in gel or cream form (eg, fluocinonide, clobetasol, or halobetasol) may help suppress acute contact dermatitis and relieve itching. This treatment should be followed by tapering of the number of applications per day or use of a mid-potency corticosteroid such as triamcinolone 0.1% cream to prevent rebound of the dermatitis. A soothing formulation is 2 oz of 0.1% triamcinolone acetonide cream in 7.5 oz Sarna lotion (0.5% camphor, 0.5% menthol, 0.5% phenol) mixed by the patient.

Subacute dermatitis (subsiding)

Mid-potency (triamcinolone 0.1%) to high-potency corticosteroids (clobetasol, amcinonide, fluocinonide, desoximetasone) are the mainstays of therapy.

Chronic dermatitis (dry and lichenified)

High-potency to superpotency corticosteroids are used in ointment form.

Systemic Therapy

For acute severe cases, prednisone may be given orally for 12–21 days. Prednisone, 60 mg for 4–7 days, 40 mg for 4–7 days, and 20 mg for 4–7 days without a further taper is one useful regimen. Another is to dispense seventy-eight 5-mg pills to be taken 12 the first day, 11 the second day, and so on. The key is to use enough corticosteroid (and as early as possible) to achieve a clinical effect and to taper slowly enough to avoid rebound. A Medrol Dosepak (methylprednisolone) with 5 days of medication is inappropriate on both counts. (See Chapter 26: Endocrine Disorders.)

Prognosis

Allergic contact dermatitis is self-limited if reexposure is prevented but often takes 2–3 weeks for full resolution.

Craig K et al. What is the best duration of steroid therapy for contact dermatitis (rhus)? J Fam Pract. 2006 Feb;55(2):166–7. [PMID: 16451787]

Mark BJ et al. Allergic contact dermatitis. Med Clin North Am. 2006 Jan;90(1):169–85. [PMID: 16310529]

Acne Vulgaris

Essentials of Diagnosis

- Occurs at puberty, though onset may be delayed into the third or fourth decade.
- Open and closed comedones are the hallmark of acne vulgaris.
- The most common of all skin conditions.
- Severity varies from purely comedonal to papular or pustular inflammatory acne to cysts or nodules.
- Face and upper trunk may be affected.
- Scarring may be a sequela of the disease or picking and manipulating by the patient.

General Considerations

Acne vulgaris is polymorphic. Open and closed comedones, papules, pustules, and cysts are found. The disease is activated by androgens in those who are genetically predisposed.

Acne vulgaris is more common and more severe in males. It does not always clear spontaneously when maturity is reached. Twelve percent of women and 3% of men over age 25 have acne vulgaris. This rate does not decrease until after age 44. The skin lesions parallel sebaceous activity. Pathogenic events include plugging of the infundibulum of the follicles, retention of sebum, overgrowth of the acne bacillus *(Propionibacterium acnes)* with resultant release of and irritation by accumulated fatty acids, and foreign body reaction to extrafollicular sebum. The mechanism of antibiotics in controlling acne is not clearly understood, but they may work because of their antibacterial or anti-inflammatory properties.

When a resistant case of acne is encountered in a woman, hyperandrogenism may be suspected. This may or may not be accompanied by hirsutism, irregular menses, or other signs of virilism. Polycystic ovary syndrome (PCOS) is the most common identifiable cause.

Clinical Findings

There may be mild soreness, pain, or itching. The lesions occur mainly over the face, neck, upper chest, back, and shoulders. Comedones are the hallmark of acne vulgaris (Plate 25). Closed comedones are tiny, flesh-colored, noninflamed bumps that give the skin a rough texture or appearance. Open comedones typically are a bit larger and have black material in them. Inflammatory papules, pustules, ectatic pores, acne cysts, and scarring are also seen (see photograph).

Plate 25.

Fig.

Acne vulgaris. (Reproduced, with permission, from Bondi EE, Jegasothy BV, Lazarus GS [editors]: *Dermatology: Diagnosis & Treatment*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Acne may have different presentations at different ages. Preteens often present with comedones as their first lesions. Inflammatory lesions in young teenagers are often found in the middle of the face, extending outward as the patient becomes older. Women in their third and fourth decades (often with no prior history of acne) commonly present with papular lesions on the chin and around the mouth.

Differential Diagnosis

In adults, acne rosacea presents with papules and pustules in the middle third of the face, but telangiectasia, flushing, and the absence of comedones distinguish this disease from acne vulgaris (see photograph). A pustular eruption on the face in patients receiving antibiotics or with otitis externa should be investigated with culture to rule out an uncommon gram-negative folliculitis. Acne may develop in patients who use systemic corticosteroids or topical fluorinated corticosteroids on the face. Acne may be exacerbated or caused by irritating creams or oils. Pustules on the face can also be caused by tinea infections. Lesions on the back are more problematic. When they occur alone, staphylococcal folliculitis, miliaria ("heat rash") or, uncommonly, *Malassezia* folliculitis should be suspected. Bacterial culture, trial of an antistaphylococcal antibiotic, and observing the response to therapy will help in the differential diagnosis. In patients with HIV infection, folliculitis is common and may be either staphylococcal folliculitis or eosinophilic folliculitis.

Fig.

Prominent rhinophyma in a patient with rosacea results from hyperplasia of soft tissues and glands of the nose. (Courtesy of K Zipperstein.)

Complications

Cyst formation, pigmentary changes in pigmented patients, severe scarring, and psychological problems may result (see photograph).

Fig.

Cystic acne associated with scarring. (Courtesy of S Goldstein.)

Treatment

General Measures

Education of the patient

When scarring seems out of proportion to the severity of the lesions, clinicians must suspect that the patient is manipulating the lesions. It is essential that the patient be educated in a supportive way about this complication. Anxiety and depression are often the underlying cause of young women excoriating minor acne. It is wise to let the patient know that at least 4–6 weeks will be required to see improvement and that old lesions may take months to fade. Therefore, improvement will be judged according to the number of new lesions forming after 6–8 weeks of therapy. Additional time will be required to see improvement on the back and chest, as these areas are slowest to respond. If hair pomades are used, they should contain glycerin and not oil. Avoid topical exposure to oils, cocoa butter (theobroma oil), and greases.

Diet

A low glycemic diet that results in weight loss has been reported to improve acne in males aged 15–25. This improvement was associated with a reduction in insulin resistance. Hyperinsulinemia has also been associated with acne in eumenorrheic women. The metabolic syndrome with insulin resistance can also be a feature of PCOS in women. This finding suggests a possible common pathogenic mechanism for acne in both adult women and men.

Comedonal Acne

Treatment of acne is based on the type and severity of lesions. Comedones require treatment different from that of pustules and cystic lesions. In assessing severity, take the sequelae of the lesions into account. An individual who gets only a few new lesions per month that scar or leave postinflammatory hyperpigmentation must be treated much more aggressively than a comparable patient whose lesions clear without sequelae. Soaps play little role in acne treatment, and unless the patient's skin is exceptionally oily, a mild soap should be used to avoid irritation that will limit the usefulness of other topicals, all of which are themselves somewhat irritating.

Topical retinoids

Tretinoin is very effective for comedonal acne or for treatment of the comedonal component of more severe acne, but its usefulness is limited by irritation. Start with 0.025% cream (not gel) and have the patient use it at first twice weekly at night, then build up to as often as nightly. A few patients cannot use even this low-strength preparation more than three times weekly but even that may cause improvement. A lentil-sized amount is sufficient to cover the entire face. To avoid irritation, have the patient wait 20 minutes after washing to apply. Adapalene gel 0.1% and reformulated tretinoin (Renova, Retin A Micro, Avita) are other options for patients irritated by standard tretinoin preparations. Some patients—especially teenagers—do best on 0.01% gel.

Although the absorption of tretinoin is minimal, its use during pregnancy is contraindicated. Some patients report photosensitivity with tretinoin. Patients should be warned that they may flare in the first 4 weeks of treatment. Tazarotene gel (0.05% or 0.1%) (Tazorac) is another topical retinoid approved for treatment of psoriasis and acne, and may be used in patients intolerant of the other retinoids.

Benzoyl peroxide

Benzoyl peroxide products are available in concentrations of 2.5%, 4%, 5%, 8%, and 10%, but it appears that 2.5% is as effective as 10% and less irritating. In general, water-based and not alcohol-based gels should be used to decrease irritation.

Antibiotics

Use of topical antibiotics (see below) has been demonstrated to decrease pustular and comedonal lesions.

Comedo extraction

Open and closed comedones may be removed with a comedo.

Papular Inflammatory Acne

Antibiotics are the mainstay for treatment of inflammatory acne. They may be used topically or orally.

The oral antibiotics of choice are tetracycline and doxycycline. Minocycline is often effective in acne unresponsive or resistant to treatment with these antibiotics but it is more expensive. Rarely, other antibiotics such as TMP-SMZ (one double-strength tablet twice daily), clindamycin (150 mg twice daily), or a cephalosporin (cefadroxil or cephalexin) may be used. Topical clindamycin phosphate and erythromycin are also used (see below). Topicals are probably the equivalent of about 500 mg/d of tetracycline given orally, which is half the usual starting dose. Topical antibiotics are used in three situations: for mild papular acne that can be controlled by topicals alone, for patients who refuse or cannot tolerate oral antibiotics, or to wean patients under good control from oral to topical preparations. To decrease resistance, benzoyl peroxide should be used in combination with the topical antibiotic.

Mild acne

The first choice of topical antibiotics in terms of efficacy and relative lack of induction of resistant *P acnes* is the combination of erythromycin or clindamycin with benzoyl peroxide topical gel. Clindamycin (Cleocin T) lotion (least irritating), gel, or solution, or one of the many brands of topical erythromycin gel or solution, may be used twice daily and the benzoyl peroxide in the morning. (A combination of erythromycin or clindamycin with benzoyl peroxide is available as a prescription item.) The addition of tretinoin 0.025% cream or 0.01% gel at night may increase improvement, since it works via a different mechanism.

Moderate acne

Tetracycline, 500 mg twice daily, doxycycline, 100 mg twice daily, and minocycline, 50–100 mg twice daily, are all effective though minocycline is more expensive. When initiating minocycline therapy, start at 100 mg in the evening for 4–7 days, then 100 mg twice daily, to decrease the incidence of vertigo. Plan a return visit in 6 weeks and at 3–4 months after that. If the patient's skin is quite clear, instructions should be given for tapering the dose by 250 mg for tetracycline, by 100 mg for doxycycline, or by 50 mg for minocycline every 6–8 weeks—while treating with topicals—to arrive at the lowest systemic dose needed to maintain clearing. In general, lowering the dose to zero without other therapy results in prompt recurrence of acne. Tetracycline, minocycline, and doxycycline are contraindicated in pregnancy, but oral erythromycin may be used.

It is important to discuss the issue of contraceptive failure when prescribing antibiotics for women taking oral contraceptives. Women may need to consider using barrier methods as well, and should report breakthrough bleeding. Oral contraceptives or spironolactone (50–200 mg daily) may be added as an antiandrogen in women with antibiotic-resistant acne or in women in whom relapse occurs after isotretinoin therapy.

Severe acne

Isotretinoin

A vitamin A analog, isotretinoin is used for the treatment of severe cystic acne that has not responded to conventional therapy. A dosage of 0.5–1 mg/kg/d for 20 weeks for a cumulative dose of at least 120 mg/kg is usually adequate for severe cystic acne. Patients should be offered isotretinoin therapy before they experience significant scarring if they are not promptly and adequately controlled by antibiotics. The drug is *absolutely contraindicated during pregnancy* because of its teratogenicity; two serum pregnancy tests should be obtained before starting the drug in a female and every month thereafter. Sufficient medication for only 1 month should be dispensed. Two forms of effective contraception must be used. Informed consent must be obtained before its use and patients must be enrolled in a monitoring program (iPledge). Side effects occur in most patients, usually related to dry skin and mucous membranes (dry lips, nosebleed, and dry eyes). If headache occurs, pseudotumor cerebri must be considered. Depression has been reported. Hypertriglyceridemia will develop in about 25% of patients, hypercholesterolemia in 15%, and a lowering of high-density lipoproteins in 5%. Minor elevations in liver function tests may develop in some patients. Fasting blood sugar may be elevated. Miscellaneous adverse reactions include decreased night vision, musculoskeletal or bowel symptoms, dry skin, thinning of hair, exuberant granulation tissue in lesions, and bony hyperostoses (seen only with very high doses or with long duration of therapy). Moderate to severe myalgias rarely necessitate decreasing the dosage or stopping the drug. Laboratory tests to be performed in all patients before treatment and after 4 weeks on therapy include cholesterol, triglycerides, and liver function studies.

Elevations of liver enzymes and triglycerides return to normal upon conclusion of therapy. The drug may induce long-term remissions in 40–60%, or acne may recur that is more easily controlled with conventional therapy. Occasionally, acne does not respond or promptly recurs after therapy, but it may clear after a second course.

Intralesional injection

In otherwise moderate acne, intralesional injection of dilute suspensions of triamcinolone acetonide (2.5 mg/mL, 0.05 mL per lesion) will often hasten the resolution of deeper papules and occasional cysts.

Laser, dermabrasion

Cosmetic improvement may be achieved by excision and punch-grafting of deep scars and by abrasion of inactive acne lesions, particularly flat, superficial scars. The technique is not without untoward effects, since hyperpigmentation, hypopigmentation, grooving, and scarring have been known to occur. Dark-skinned individuals do poorly. Corrective surgery within 12 months after isotretinoin therapy may not be advisable. Active acne of all types can be treated with certain laser and photodynamic therapies. This can be considered when standard treatments are contraindicated or fail.

Prognosis

Acne vulgaris eventually remits spontaneously, but when this will occur cannot be predicted. The condition may persist throughout adulthood and may lead to severe scarring if left untreated. Patients treated with antibiotics continue to improve for the first 3–6 months of therapy. Relapse during treatment may suggest the emergence of resistant *P acnes*. The disease is chronic and tends to flare intermittently in spite of treatment. Remissions following systemic treatment with isotretinoin may be lasting in up to 60% of cases. Relapses after isotretinoin usually occur within 3 years and require a second course in up to 20% of patients.

Rosacea

Essentials of Diagnosis

- A chronic facial disorder.
- A neurovascular component (erythema and telangiectasis and a tendency to flush easily).
- An acneiform component (papules and pustules) may also be present.
- A glandular component accompanied by hyperplasia of the soft tissue of the nose (rhinophyma) (see photograph).

General Considerations

The pathogenesis of this disorder is not known. Topical corticosteroids applied to the lower face can induce rosacea-like conditions (see photograph).

Fig.

This eruption resembling rosacea occurred following topical use of a steroid cream. (Courtesy of S Goldstein.)

Clinical Findings

Patients frequently report flushing or exacerbation of their rosacea by heat or cold, hot drinks, spicy food, sunlight, exercise, alcohol, emotions, and menopausal flushing. The cheeks, nose, and chin—at times the entire face—may have a rosy hue. No comedones are seen. In its mildest form, erythema and dilated vessels are seen on the cheeks. Inflammatory papules may be superimposed on this background and may evolve to pustules (Plate 26); (see photograph). Associated seborrhea may be found. The patient often complains of burning or stinging with episodes of flushing. Patients may have associated ophthalmic disease, including blepharitis and keratitis, that often requires systemic antibiotic therapy.

Plate 26.

Dermatology, UCSF.)

Fig.

Acne rosacea. (Reproduced, with permission, from Bondi EE, Jegasothy BV, Lazarus GS [editors]: *Dermatology: Diagnosis & Treatment*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Differential Diagnosis

Rosacea is distinguished from acne by the presence of the neurovascular component and the absence of comedones (see photograph). The rosy hue of rosacea and telangiectasis will pinpoint the diagnosis. Lupus is often misdiagnosed, but the presence of pustules excludes that diagnosis.

Treatment

Educating patients to avoid the factors they know to produce exacerbations is important. Patients should wear a broad-spectrum sunscreen with UVA coverage; however, exquisite sensitivity to topical preparations may limit patient options. Zinc- or titanium-based sunscreens are better tolerated, and barrier protective silicones in the sunblock may enhance tolerance. Medical management is effective only for the inflammatory papules and pustules and the erythema that surrounds them. Rosacea is usually a lifelong condition, so maintenance therapy is required.

Local Therapy

Metronidazole (available as creams, gels, or lotions), 0.75% applied twice daily or 1% applied once daily, is the topical treatment of choice. If metronidazole is not tolerated, topical clindamycin (solution, gel, or lotion) 1% applied twice daily is effective. Response is noted in 4–8 weeks. Sulfur-sodium sulfacetamide-containing topicals are helpful in patients only partially responsive to topical antibiotics. Benzoyl peroxide, as in acne vulgaris, may be helpful in reducing the pustular component. Topical retinoids can be carefully added for maintenance.

Systemic Therapy

Tetracycline, 250 or 500 mg orally twice daily on an empty stomach, should be used when topical therapy is inadequate. Minocycline or doxycycline, 50–100 mg daily to twice daily, is also effective. Metronidazole or amoxicillin, 250–500 mg twice daily, may be used in refractory cases. Side effects are few, although metronidazole may produce a disulfiram-like effect when the patient ingests alcohol and it may cause neuropathy with long-term use. Isotretinoin may succeed where other measures fail. A dosage of 0.5 mg/kg/d orally for 12–28 weeks is recommended. See precautions above. Telangiectasias are benefitted by laser therapy, and phymatous overgrowth of the nose can be treated by surgical reduction.

Prognosis

Rosacea tends to be a persistent process. With the regimens described above, it can usually be controlled adequately.

van Zuuren EJ et al. Systematic review of rosacea treatments. J Am Acad Dermatol. 2007 Jan;56(1):107–15. [PMID: 17190628]

Folliculitis (Including Sycosis)

Essentials of Diagnosis

- Itching and burning in hairy areas.
- Pustules in the hair follicles.

General Considerations

Folliculitis has multiple causes. It is frequently caused by staphylococcal infection and may be more common in the diabetic patient. When the lesion is deep-seated, chronic, and recalcitrant on the head and neck, it is called sycosis.

Gram-negative folliculitis, which may develop during antibiotic treatment of acne, may present as a flare of acne pustules or nodules. *Klebsiella*, *Enterobacter*, *Escherichia coli*, and *Proteus* have been isolated from these lesions.

"Hot tub folliculitis," caused by *Pseudomonas aeruginosa*, is characterized by pruritic or tender follicular, pustular lesions occurring within 1–4 days after bathing in a contaminated hot tub, whirlpool, or public swimming pool (see photograph). Rarely, systemic infections may result. Neutropenic patients should avoid these exposures.

Fig.

Hot tub folliculitis presenting as tender follicular and pustular lesions two days after the patient was in a hot tub. (Courtesy of S Goldstein.)

Nonbacterial folliculitis may also be caused by friction and oils. Occlusion, perspiration, and rubbing, such as that resulting from tight jeans and other heavy fabrics on the upper legs can worsen this type of folliculitis.

Steroid acne may be seen during topical or systemic corticosteroid therapy.

A form of sterile folliculitis called eosinophilic folliculitis consisting of urticarial papules with prominent eosinophilic infiltration is common in patients with AIDS. It may appear first with institution of highly active antiretroviral therapy (HAART) and be mistaken for a drug eruption.

Pseudofolliculitis is caused by ingrowing hairs in the beard area. It occurs in men and women with tightly curled beard hair. In this entity, the papules and pustules are located at the side of and not in follicles. It may be treated by growing a beard, by using chemical depilatories, or by shaving with a foil-guard razor. Laser hair removal is dramatically beneficial in patients with pseudofolliculitis, requires limited maintenance, and can be done on patients of any skin color. Pseudofolliculitis is a true medical indication for such a procedure and should not be considered cosmetic.

Clinical Findings

The symptoms range from slight burning and tenderness to intense itching. The lesions consist of pustules of hair follicles (Plate 27); (see micrograph).

Plate 27.

Bacterial folliculitis. (Used, with permission, from Berger TG, Dept. Dermatology, UCSF.)

Fig.
Folliculitis. A follicle is virtually completely destroyed and replaced by a neutrophilic abscess. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Differential Diagnosis

It is important to differentiate bacterial from nonbacterial folliculitis. The history is important for pinpointing the causes of nonbacterial folliculitis, and a Gram stain and culture are indispensable. One must differentiate folliculitis from acne vulgaris (see photograph) or pustular miliaria (heat rash) (see photograph) and from infections of the skin such as impetigo or fungal infections. Pseudomonas folliculitis is often suggested by the history of hot tub use. Eosinophilic folliculitis in

AIDS often requires biopsy for diagnosis.

Fig.

An example of miliaria crystallina denoted by vesicular eruption over the trunk of this patient. Miliaria rubra can simulate folliculitis. (Courtesy of I Frieden.)

Complications

Abscess formation is the major complication of bacterial folliculitis.

Prevention

Correct any predisposing local causes such as oils or friction. Be sure that the water in hot tubs and spas is treated properly. If staphylococcal folliculitis is persistent, treatment of nasal or perineal carriage with rifampin, 600 mg daily for 5 days, or with topical mupirocin ointment 2% twice daily for 5 days, may help. Prolonged oral clindamycin, 150–300 mg/d for 4–6 weeks, or oral TMP-SMZ given 1 week per month for 6 months can be effective in preventing recurrent staphylococcal folliculitis and furunculosis. Bleach baths ($^{1}/_{2}$ to 1 cup per 20 liters of bathwater for 15 minutes 3–5 times weekly) may reduce cutaneous staphylococcal carriage and not contribute to antibiotic resistance. Control of blood glucose in diabetes may reduce the number of these infections.

Treatment

Local Measures

Anhydrous ethyl alcohol containing 6.25% aluminum chloride (Xerac AC), applied to lesions and environs, may be helpful, especially for chronic frictional folliculitis of the buttocks. Topical antibiotics are generally ineffective if bacteria have invaded the hair follicle.

Specific Measures

Pseudomonas folliculitis will clear spontaneously in non-neutropenic patients if the lesions are superficial. It may be treated with ciprofloxacin, 500 mg twice daily for 5 days.

Systemic antibiotics are recommended for bacterial folliculitis due to other organisms. Extended periods of treatment (4–8 weeks or more) with antistaphylococcal antibiotics are required if infection has involved the scalp or densely hairy areas such as the axilla, beard, or groin.

Gram-negative folliculitis in acne patients may be treated with isotretinoin in compliance with all precautions discussed above (see Acne Vulgaris).

Eosinophilic folliculitis may be treated initially by the combination of potent topical corticosteroids and oral antihistamines. In more severe cases, treatment is with one of the following: topical permethrin (application for 12 hours every other night for 6 weeks); itraconazole, 200–400 mg daily; UVB or PUVA phototherapy; or isotretinoin, 0.5 mg/kg/d for up to 5 months. A remission may be induced by some of these therapies, but long-term treatment may be required.

Prognosis

Bacterial folliculitis is occasionally stubborn and persistent, requiring prolonged or intermittent courses of antibiotics.

Nervi SJ et al. Eosinophilic pustular folliculitis: a 40 year retrospect. J Am Acad Dermatol. 2006 Aug;55(2):285–9. [PMID: 16844513]

Miliaria (Heat Rash)

Essentials of Diagnosis

- Burning, itching, superficial aggregated small vesicles, papules, or pustules on covered areas of the skin, usually the trunk.
- More common in hot, moist climates.
- Rare forms associated with fever and even heat prostration.

General Considerations

Miliaria occurs most commonly on the trunk and intertriginous areas. A hot, moist environment is the most frequent cause. Bedridden febrile patients are susceptible. Plugging of the ostia of sweat ducts occurs, with ultimate rupture of the sweat duct, producing an irritating, stinging reaction. Increase in numbers of resident aerobes, notably cocci, plays a role. Drugs that enhance sweat gland function (eg, clonidine, -blockers, opiates), may contribute.

Clinical Findings

The usual symptoms are burning and itching. The lesions consist of small, superficial, red, thin-walled, discrete vesicles (miliaria crystallina), papules (miliaria rubra), or vesicopustules or pustules (miliaria pustulosa) (see photograph). The reaction virtually always affects the back in a hospitalized patient.

Differential Diagnosis

Miliaria is to be distinguished from drug eruption and folliculitis.

Prevention

Use of an antibacterial preparation such as chlorhexidine prior to exposure to heat and humidity may help prevent the condition. Frequent turning or sitting of the hospitalized patient may reduce miliaria on the back.

Treatment

The patient should keep cool and wear light clothing. Triamcinolone acetonide, 0.1% in Sarna lotion, or a mid-potency corticosteroid in a lotion or cream should be applied two to four times daily. Secondary infections (superficial pyoderma) are treated with appropriate antistaphylococcal antibiotics. Anticholinergic drugs given by mouth may be helpful in severe cases, eg, glycopyrrolate, 1 mg twice daily.

Prognosis

Miliaria is usually a mild disorder, but severe forms (tropical anhidrosis and asthenia) result from interference with the heat-regulating mechanism.

Howe AS et al. Heat-related illness in athletes. Am J Sports Med. 2007 Aug;35(8):1384–95. [PMID: 17609528]

Mucocutaneous Candidiasis

Essentials of Diagnosis

- Severe pruritus of vulva, anus, or body folds.
- Superficial denuded, beefy-red areas with or without satellite vesicopustules.

- Whitish curd-like concretions on the oral and vaginal mucous membranes.
- Yeast and pseudohyphae on microscopic examination of scales or curd.

General Considerations

Mucocutaneous candidiasis is a superficial fungal infection that may involve almost any cutaneous or mucous surface of the body. It is particularly likely to occur in diabetics, during pregnancy, and in obese persons who perspire freely. Systemic antibiotics, oral corticosteroids, and oral contraceptive agents may be contributory. Oral candidiasis may be the first sign of HIV infection (see Chapter 31: HIV Infection & AIDS).

Clinical Findings

Symptoms and Signs

Itching may be intense. Burning is reported, particularly around the vulva and anus. The lesions consist of superficially denuded, beefy-red areas in the depths of the body folds such as in the groin and the intergluteal cleft, beneath the breasts, at the angles of the mouth, and in the umbilicus (Plate 28). The peripheries of these denuded lesions are superficially undermined, and there may be satellite vesicopustules. Whitish, curd-like concretions may be present on mucosal lesions (see photograph). Paronychia may occur (Plate 29).

Plate 29.

Acute paronychia. (Courtesy of EJ Mayeaux, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family*

Medicine. McGraw-Hill, 2009.)

Laboratory Findings

Clusters of budding cells and pseudohyphae can be seen under high power when skin scales or curd-like lesions have been cleared in 10% KOH (see micrograph). Culture can confirm the diagnosis.

Differential Diagnosis

Intertrigo (see photograph), seborrheic dermatitis (see photograph), tinea cruris, "inverse psoriasis" (see photograph), and erythrasma involving the same areas may mimic mucocutaneous candidiasis (see photograph).

Complications

Systemic invasive candidiasis with candidemia may be seen with immunosuppression and in patients receiving broad-spectrum antibiotic and hypertonic glucose solutions, as in hyperalimentation. There may or may not be clinically evident mucocutaneous candidiasis.

Treatment

General Measures

Affected parts should be kept dry and exposed to air as much as possible. If possible, discontinue systemic antibiotics. For treatment of systemic invasive candidiasis, see Chapter 36: Mycotic Infections.

Local Measures

Nails and paronychia

Apply clotrimazole solution 1% twice daily. Thymol 4% in ethanol applied once daily is an alternative.

Skin

Apply nystatin ointment or clotrimazole cream 1%, either with hydrocortisone cream 1%, twice daily.

Vulvar and anal mucous membranes

For vaginal candidiasis, single-dose fluconazole (150 mg) is effective. Intravaginal clotrimazole, miconazole, terconazole, or nystatin may also be used. Long-term suppressive therapy may be required for recurrent or "intractable" cases. Non-*albicans* candidal species may be identified by culture in some refractory cases and may respond to oral itraconazole, 200 mg twice daily for 2–4 weeks.

Balanitis

This is most frequent in uncircumcised men, and *Candida* usually plays a role. Topical nystatin ointment is the initial treatment if the lesions are mildly erythematous or superficially erosive. Soaking with dilute aluminum acetate for 15 minutes twice daily may quickly relieve burning or itching. Chronicity and relapses, especially after sexual contact, suggest reinfection from a sexual partner who should be treated. Severe purulent balanitis is usually due to bacteria. If it is so severe that phimosis occurs, oral antibiotics—some with activity against anaerobes—are required; if rapid improvement does not occur, urologic consultation is indicated.

Mastitis

Lancinating breast pain and nipple dermatitis in breastfeeding women may be a manifestation of *Candida* colonization/infection of the breast ducts. Treatment with oral fluconazole, 200 mg/d can be dramatically effective.

Prognosis

Cases of cutaneous candidiasis range from the easily cured to the intractable and prolonged.

Urticaria & Angioedema

Essentials of Diagnosis

- Eruptions of evanescent wheals or hives.
- Itching is usually intense but may on rare occasions be absent.
- Special forms of urticaria have special features (dermatographism, cholinergic urticaria, solar urticaria, or cold urticaria).
- Most incidents are acute and self-limited over a period of 1–2 weeks.
- Chronic urticaria (episodes lasting > 6 weeks) may have an autoimmune basis.

General Considerations

Urticaria can result from many different stimuli on an immunologic or nonimmunologic basis. The most common immunologic mechanism is mediated by IgE, as seen in the majority of patients with acute urticaria; another involves activation of the complement cascade. Some patients with chronic urticaria demonstrate autoantibodies directed against mast cell IgE receptors. Angiotensin-converting enzyme inhibitor and angiotensin II receptor antagonist therapy may be complicated by urticaria or angioedema. In general, extensive costly workups are not indicated in patients who have urticaria. A careful history and physical examination are more helpful.

Clinical Findings

Symptoms and Signs

Lesions are itchy red swellings of a few millimeters to many centimeters (Plate 30). The morphology of the lesions may vary over a period of minutes to hours, resulting in geographic or bizarre patterns (see photograph); (see photograph). Individual lesions in true urticaria last less than 24 hours, and often only 2–4 hours. Angioedema is involvement of deeper subcutaneous tissue with swelling of the lips, eyelids, palms, soles, and genitalia. Angioedema is no more likely than urticaria to be associated with systemic complications such as laryngeal edema or hypotension. In cholinergic urticaria, triggered by a rise in core body temperature (hot showers, exercise), wheals are 2–3 mm in diameter with a large surrounding red flare. Cold urticaria is acquired or inherited and triggered by exposure to cold and wind (see Chapter 37: Disorders Due to Physical Agents).

Laboratory Findings

Laboratory studies are not likely to be helpful in the evaluation of acute or chronic urticaria. The most common causes of acute urticaria are foods, infections, and medications. The cause of chronic urticaria is often not found. In patients with individual slightly purpuric lesions that persist past 24 hours, skin biopsy may confirm neutrophilic urticaria or urticarial vasculitis. A functional ELISA test can detect patients with an autoimmune basis for their chronic urticaria.

Differential Diagnosis

Papular urticaria resulting from insect bites persists for days. A central punctum can usually be seen. Streaked urticarial lesions may be seen in the 24–48 hours before blisters appear in acute allergic plant dermatitis, eg, poison ivy, oak, or sumac (see photograph). Urticarial response to heat, sun, water, and pressure are quite rare. Urticarial vasculitis may be seen as part of serum sickness, associated with fever and arthralgia. In this setting, a low serum complement level may be associated with severe systemic disease.

In hereditary angioedema, there is generally a positive family history and gastrointestinal or respiratory symptoms. Urticaria is not part of the syndrome, and lesions are not pruritic.

Treatment

General Measures

A detailed search by history for a cause of acute urticaria should be undertaken, and treatment may then be tailored to include the provocative condition. The chief causes are drugs—eg, aspirin, NSAIDs, morphine, and codeine; arthropod bites—eg, insect bites and bee stings (though the latter may cause anaphylaxis as well as angioedema); physical factors such as heat, cold, sunlight, and pressure; and, presumably, neurogenic factors, as in cholinergic urticaria induced by exercise, excitement, hot showers, etc. Other causes may include penicillins and other medications; inhalants such as feathers and animal danders; ingestion of shellfish, tomatoes, or strawberries; vaccines; external contactants, including various chemicals and cosmetics; and infections such as viral hepatitis (causing urticarial vasculitis).

Systemic Treatment

The mainstay of treatment initially includes H_1-antihistamines (see above). Initial therapy is hydroxyzine, 10 mg twice daily to 25 mg three times daily, or as one dose of 50–75 mg at night to reduce sedation. Cyproheptadine, 4 mg four times daily, may be especially useful for cold urticaria. "Nonsedating" or less sedating antihistamines are added if the generic sedating antihistamines are not effective. Options include fexofenadine, 60 mg twice daily (or 180 mg once daily); or loratadine, 10 mg/d. Higher doses of these second-generation antihistamines may be required to suppress urticaria (up to four times the standard recommended dose) than are required for allergic rhinitis. These high doses are safe and can be used in refractory cases. Cetirizine, a metabolite of hydroxyzine, is less sedating (13% of patients) and is given in a dosage of 10 mg/d.

Doxepin (a tricyclic antidepressant), 10–75 mg at bedtime, can be very effective in chronic urticaria. It has anticholinergic side effects.

H_2-antihistamines in combination with H_1-blockers may be helpful in patients with symptomatic dermatographism and to a lesser degree in chronic urticaria. UVB phototherapy can suppress some cases of chronic urticaria.

A few patients with chronic urticaria may respond to elimination of salicylates and tartrazine (coloring agent). Asymptomatic foci of infection—sinusitis, vaginal candidiasis, cholecystitis, and intestinal parasites—may rarely cause chronic urticaria. Systemic corticosteroids in a dose of about 40 mg daily will usually suppress acute and chronic urticaria. However, the use of corticosteroids is rarely indicated, since properly selected combinations of antihistamines with less toxicity are usually effective. Once corticosteroids are withdrawn, the urticaria virtually always returns if it had been chronic. Instead of instituting systemic corticosteroids, consultation should be sought from a dermatologist or allergist with experience in managing severe urticaria. Cyclosporine (3–5 mg/kg/d) may be effective in severe cases of autoimmune chronic urticaria.

Local Treatment

Local treatment is rarely rewarding.

Prognosis

Acute urticaria usually lasts only a few days to weeks. Half of patients whose urticaria persists for more than 6 weeks will have it for years.

Erythema Multiforme

Essentials of Diagnosis

- Sudden onset of symmetric erythematous skin lesions with history of recurrence.
- May be macular, papular, urticarial, bullous, or purpuric.
- "Target" lesions with clear centers and concentric erythematous rings or "iris" lesions may be noted in erythema multiforme minor. These are rare in drug-associated erythema multiforme major (Stevens-Johnson syndrome).
- Erythema multiforme minor on extensor surfaces, palms, soles, or mucous membranes. Erythema multiforme major favors the trunk.
- Herpes simplex is the most common cause of erythema multiforme minor.
- Drugs are the most common cause of erythema multiforme major in adults.

General Considerations

Erythema multiforme is an acute inflammatory skin disease. Erythema multiforme is divided clinically into minor and major types based on the clinical findings. Approximately 90% of cases of erythema multiforme minor follow outbreaks of herpes simplex, and so is now preferably termed "herpes-associated erythema multiforme" (HAEM). The term "erythema multiforme major" has been replaced by three terms: Stevens-Johnson syndrome, with less than 10% BSA skin loss; toxic epidermal necrolysis when there is greater than 30% BSA skin loss; and Stevens-Johnson syndrome/toxic epidermal necrolysis overlap for cases with between 10% and 30% BSA denudation. All these clinical scenarios are characterized by toxicity and involvement of two or more mucosal surfaces (often oral and conjunctival). They are most often caused by drugs, especially sulfonamides, NSAIDs, allopurinol, and anticonvulsants. *Mycoplasma pneumoniae* may trigger a skin eruption closely resembling Stevens-Johnson syndrome and may be the cause of Stevens-Johnson syndrome in up to 50% of children in some series. Erythema multiforme may also present as chronic or recurring ulceration localized to the oral mucosa, with skin lesions present in only half of the cases. The exposure to drugs associated with erythema multiforme may be systemic or topical (eg, eyedrops).

Clinical Findings

Symptoms and Signs

A classic target lesion, found most commonly in herpes-associated erythema multiforme, consists of three concentric zones of color change, most often found acrally on the hands and feet (Plate 31); (see photograph). Not all lesions will have this appearance. Drug-associated bullous eruptions in the Stevens-Johnson syndrome/toxic epidermal necrolysis spectrum present with raised purpuric target-like lesions, with only two zones of color change and a central blister, or nondescript reddish or purpuric macules (see photograph); (see photograph). Pain on eating, swallowing, and urination can occur if the appropriate mucosae are involved (see photograph). Inability to eat is common if the oral mucosa is extensively involved.

Fig.

Patient with erythema multiforme major demonstrating oral lesions on lips, buccal mucosa, and tongue. (Courtesy of S Goldstein.)

Laboratory Findings

Blood tests are not useful for diagnosis. Skin biopsy is diagnostic. Direct immunofluorescence studies are negative.

Differential Diagnosis

Urticaria and drug eruptions are the chief entities that must be differentiated from erythema multiforme minor (see photograph). Individual lesions of true urticaria should come and go within 24 hours and are usually responsive to antihistamines. In erythema multiforme major, the differential diagnosis includes autoimmune bullous diseases (including pemphigus and pemphigoid) and acute generalized exanthematous pustulosis (see photograph); (see photograph). The presence of a blistering eruption requires biopsy and consultation for appropriate diagnosis and treatment.

Complications

The tracheobronchial mucosa and conjunctiva may be involved in severe cases with resultant scarring. Ophthalmologic consultation is required if ocular involvement is present.

Treatment

General Measures

Toxic epidermal necrolysis is best treated in a burn unit. Otherwise, patients need not be admitted unless mucosal involvement interferes with hydration and nutrition. Patients who begin to blister should be seen daily. Open lesions should be managed like second-degree burns. Immediate discontinuation of the inciting medication (before blistering occurs) is a significant predictor of outcome. Delay in establishing the diagnosis and inadvertently continuing the offending medication results in higher morbidity and mortality.

Specific Measures

The most important aspect of treatment is to stop the offending medication and to move patients with more than 25–30% BSA involvement to a burn unit. Nutritional and fluid support and high vigilance for infection are the most important aspects of care. Recent reviews of systemic treatments for Stevens-Johnson syndrome and toxic epidermal necrolysis have been conflicting, but the largest series have failed to show statistically significant benefit with treatment. Some data support the use of high-dose corticosteroids. If corticosteroids are to be tried in more severe cases, they should be used early, before blistering occurs, and in moderate to high doses (prednisone, 100–250 mg) and stopped within days if there is no dramatic response. Intravenous immunoglobulin (IVIG) (0.75 g/kg/d for 4 days) has become standard of care at some centers for toxic epidermal necrolysis cases and can be considered in cases with greater than 30% BSA involvement. It has not been proven to reduce mortality. Oral and topical corticosteroids are useful in the oral variant of erythema multiforme. Oral acyclovir prophylaxis of herpes simplex infections may be effective in preventing recurrent herpes-associated erythema multiforme minor.

Local Measures

Topical therapy is not very effective in this disease. For oral lesions, 1% diphenhydramine elixir mixed with Kaopectate or with 1% dyclonine may be used as a mouth rinse several times daily.

Prognosis

Erythema multiforme minor usually lasts 2–6 weeks and may recur. Erythema multiforme major may be serious with a mortality of about 30% in cases with greater than 30% BSA involvement.

Erythema Migrans

Erythema migrans (see also Chapter 34: Spirochetal Infections) is a unique cutaneous eruption that characterizes the localized or generalized early stage of Lyme disease (borreliosis). Three to 32 days (median: 7 days) after a tick bite, there is gradual expansion of redness around the papule representing the bite site (Plate 32). The advancing border is usually slightly raised, warm, red to bluish-red, and free of any scale. Centrally, the site of the bite may clear, leaving only a rim of peripheral erythema, or it may become indurated, vesicular, or necrotic. The annular erythema usually grows to a median diameter of 15 cm (range: 3–68 cm, but virtually always > 5 cm). It is accompanied by a burning sensation in half of patients; rarely, it is pruritic or painful. Multiple secondary annular lesions similar in appearance to the primary lesion but without indurated centers and generally of smaller size will develop in 20% of patients. In the southeastern United States, similar lesions are seen in patients who are not as ill and who tend to have classic central clearing of their lesions. These patients have negative Lyme serology tests. This condition has been called Southern tick-associated rash illness [STARI]. This illness is transmitted by the lonestar tick; some cases are caused by *Borrelia lonestari*, for which the white tail deer is the animal reservoir. Systemic symptoms are uncommon in STARI and the skin lesions respond to the same antibiotic agents used for Lyme disease, suggesting that a spirochete (probably as yet unidentified *Borrelia* species) is causative in all these cases.

Plate 32.
Erythema migrans due to *Borrelia burgdorferi* (Lyme disease). (Courtesy of James Gathany, Public Health

Image Library, CDC.)

Without treatment, erythema migrans and the secondary lesions fade in a median of 28 days, though some may persist for months. Ten percent of untreated patients experience recurrences over the ensuing months. Treatment with systemic antibiotics (see Table 34–4) is necessary to prevent systemic involvement. However, only 60–70% of those with systemic involvement have experienced erythema migrans.

Erysipelas

Essentials of Diagnosis

- Edematous, spreading, circumscribed, hot, erythematous area, with or without vesicles or bullae.
- Central face frequently involved.
- Pain, chills, fever, and systemic toxicity may be striking.

General Considerations

Erysipelas is a superficial form of cellulitis that occurs classically on the cheek, caused by -hemolytic streptococci.

Clinical Findings

Symptoms and Signs

The symptoms are pain, malaise, chills, and moderate fever. A bright red spot appears first, very often near a fissure at the angle of the nose. This spreads to form a tense, sharply demarcated, glistening, smooth, hot plaque (Plate 33); (see photograph). The margin characteristically makes noticeable advances in days or even hours. The lesion is somewhat edematous and can be pitted slightly with the finger. Vesicles or bullae occasionally develop on the surface. The lesion does not usually become pustular or gangrenous and heals without scar formation. The disease may complicate any break in the skin that provides a portal of entry for the organism.

Plate 33.
Erysipelas (cellulitis). (Used, with permission, from Berger TG, Dept. Dermatology, UCSF.)

Fig.
Characteristic features of erysipelas present in this patient include an advancing, edematous, well-circumscribed erythema on the face. (Courtesy of S Goldstein.)

Laboratory Findings

Leukocytosis is almost invariably present; blood cultures may be positive.

Differential Diagnosis

Erysipeloid is a benign bacillary infection producing cellulitis of the skin of the fingers or the backs of the hands in fishermen and meat handlers.

Complications

Unless erysipelas is promptly treated, death may result from extension of the process and systemic toxicity, particularly in the elderly.

Treatment

Place the patient at bed rest with the head of the bed elevated. Intravenous antibiotics effective against group A -hemolytic streptococci and staphylococci are indicated for the first 48 hours in all but the mildest cases. A 7-day course is completed with penicillin VK, 250 mg, dicloxacillin, 250 mg, or a first-generation cephalosporin, 250 mg, orally four times a day. Alternatives in penicillin-allergic patients are clindamycin or erythromycin, the latter only if the infection is known to be due to streptococci.

Prognosis

Erysipelas was at one time a life-threatening infection. It can now usually be quickly controlled with systemic penicillin or erythromycin therapy (see references under Cellulitis).

Leclerc S et al. Recurrent erysipelas: 47 cases. Dermatology. 2007;214(1):52–7. [PMID: 17191048]

Cellulitis

Essentials of Diagnosis

- Edematous, expanding, erythematous, warm plaque with or without vesicles or bullae.
- Lower leg is frequently involved.
- Pain, chills, and fever are commonly present.
- Septicemia may develop.

General Considerations

Cellulitis, a diffuse spreading infection of the dermis and subcutaneous tissue, is usually on the lower leg and most commonly due to gram-positive cocci, especially group A -hemolytic streptococci and *S aureus*. Rarely, gram-negative rods or even fungi can produce a similar picture.

In otherwise healthy persons, the most common portal of entry for lower leg cellulitis is toe web intertrigo with fissuring. Venous insufficiency can also predispose to lower leg cellulitis. Injection drug use and open ulcerations may also be complicated by cellulitis. Cellulitis in the diabetic foot may be a major problem and is often associated with neuropathy and hyperkeratotic nodules from ill-fitting shoes and abnormal weight bearing.

Clinical Findings

Symptoms and Signs

Cellulitis begins as a small patch, which from its onset is tender. Swelling, erythema, and pain are often present. The lesion expands over hours, so that from onset to presentation is usually 6 to 36 hours. As the lesion grows, the patient becomes more ill with progressive chills, fever, and malaise. If septicemia develops, hypotension may develop, followed by shock.

Laboratory Findings

Leukocytosis or at least a neutrophilia (left shift) is present from early in the course. Blood cultures may be positive. If a central ulceration, pustule, or abscess is present, culture may be of value. Aspiration of the advancing edge has a low yield (20%) and is usually not performed. Instead, if an unusual organism is suspected and there is no loculated site to culture, a full thickness skin biopsy taken before antibiotics are given can be useful. Part is cultured and part processed for histologic evaluation with Gram stain. This technique is particularly useful in the immunocompromised patient. If a primary source for the infection is identified (wound, leg ulcer, toe web intertrigo), cultures from these sites isolate the causative pathogen in half of cases and can be used to guide antibiotic therapy.

Differential Diagnosis

Two potentially life threatening entities that can mimic cellulitis (ie, present with a painful, red, swollen lower extremity) include deep venous thrombosis and necrotizing fasciitis. The diagnosis of necrotizing fasciitis should be suspected in a patient who has a very toxic appearance, bullae, crepitus or anesthesia of the involved skin, overlying skin necrosis, and laboratory evidence of rhabdomyolysis (elevated creatine kinase [CK]) or disseminated intravascular coagulation. While these findings may be present with severe cellulitis and bacteremia, it is essential to rule out necrotizing fasciitis because rapid surgical debridement is essential. Other skin lesions that may resemble cellulitis include sclerosing panniculitis, an acute, exquisitely tender red plaque on the medial lower legs above the malleolus in patients with venous stasis or varicosities, and acute severe contact dermatitis on a limb, which produces erythema, vesiculation, and edema as seen in cellulitis, but with itching instead of pain.

Treatment

Intravenous or parenteral antibiotics may be required for the first 2–5 days, with adequate coverage for *Streptococcus* and *Staphylococcus*. Hospitalization is required in cases with severe local symptoms and signs, hypotension, elevated serum creatinine, low serum bicarbonate, elevated creatine kinase, elevated white blood cell count with marked left shift, or elevated C-reactive protein. If CA-MRSA is suspected, therapy is vancomycin, clindamycin, or TMP-SMZ plus a -lactam. In mild cases or following the initial parenteral therapy, dicloxacillin or cephalexin, 250–500 mg four times daily for 5–10 days, is usually adequate. If MRSA is suspected, use of TMP-SMZ, clindamycin, or the combination of doxycycline plus rifampin should be considered. In patients in whom intravenous treatment is not instituted, the first dose of oral antibiotic can be doubled to achieve rapid high blood levels.

Gabillot-Carre M et al. Acute bacterial skin infections and cellulitis. Curr Opin Infect Dis. 2007 Apr;20(2):118–23. [PMID: 17496568]

Pemphigus

Essentials of Diagnosis

- Relapsing crops of bullae.
- Often preceded by mucous membrane bullae, erosions, and ulcerations.
- Superficial detachment of the skin after pressure or trauma variably present (Nikolsky sign).
- Acantholysis on biopsy.
- Immunofluorescence studies are confirmatory.

General Considerations

Pemphigus is an uncommon intraepidermal blistering disease occurring on skin and mucous membranes. It is caused by autoantibodies to adhesion molecules expressed in the skin and mucous membranes. The cause is unknown, and in the preantibiotic, presteroid era, the condition was usually fatal within 5 years. The bullae appear spontaneously and are tender and painful when they rupture. Drug-induced pemphigus from penicillamine, captopril, and others has been reported. There are several forms of pemphigus: **pemphigus vulgaris** and its variant, **pemphigus vegetans;** and the more superficially blistering **pemphigus foliaceus** and its variant, **pemphigus erythematosus.** All forms may occur at any age but most commonly in middle age. The vulgaris form begins in the mouth in over 50% of cases. The foliaceus form is especially apt to be associated with other autoimmune diseases, or it may be drug-induced. Paraneoplastic pemphigus, a unique form of the disorder, is associated with numerous types of benign and malignant neoplasms but most frequently non-Hodgkin lymphoma.

Clinical Findings

Symptoms and Signs

Pemphigus is characterized by an insidious onset of flaccid bullae, crusts, and erosions in crops or waves (Plate 34); (see photograph). In pemphigus vulgaris, lesions often appear first on the oral mucous membranes. These rapidly become erosive. The scalp is another site of early involvement. Rubbing a cotton swab or finger laterally on the surface of uninvolved skin may cause easy separation of the epidermis **(Nikolsky sign).**

Plate 34.

Pemphigus. (Used, with permission, from Berger TG, Dept. Dermatology, UCSF.)

Laboratory Findings

The diagnosis is made by light microscopy and by direct and indirect immunofluorescence (IIF) microscopy. Autoantibodies to intercellular adhesion molecules can be detected with ELISA assays and have replaced the use of IIF in some centers.

Differential Diagnosis

Blistering diseases include erythema multiforme (see photograph), drug eruptions, bullous impetigo, contact dermatitis (see photograph), dermatitis herpetiformis (see photograph), and bullous pemphigoid (see photograph), but flaccid blisters are not typical of these diseases, and acantholysis is not seen on biopsy. All of these diseases have clinical characteristics and different immunofluorescence test results that distinguish them from pemphigus.

Paraneoplastic pemphigus is clinically, histologically, and immunologically distinct from other forms of the disease. Oral erosions and erythematous plaques resembling erythema multiforme are seen. Survival rates are low because of the underlying malignancy.

Complications

Secondary infection commonly occurs; this is a major cause of morbidity and mortality. Disturbances of fluid, electrolyte, and nutritional intake can occur as a result of painful oral ulcers.

Treatment

General Measures

When the disease is severe, hospitalize the patient at bed rest and provide antibiotics and intravenous feedings as indicated. Anesthetic troches used before eating ease painful oral lesions.

Systemic Measures

Pemphigus very often requires systemic therapy as early in its course as possible. However, the main morbidity in this disease is due to the side effects of such therapy. Initial therapy is with systemic corticosteroids: prednisone, 60–80 mg daily. In all but the most mild cases, a steroid-sparing agent is added from the beginning, since the course of the disease is long and the steroid-sparing agents take several weeks to exert their activity. Azathioprine (100–200 mg daily) or mycophenolate mofetil (1–1.5 g twice daily) is used most frequently, the latter seeming to be the most reliable and recommended for most cases. Rituximab may be given in refractory cases to diminish the amount of autoantibody production. If this fails, monthly IVIG at 2 g/kg intravenously over 3 days with rituximab is dramatically beneficial and has replaced high-dose corticosteroids plus cyclophosphamide and pulse intravenous corticosteroids as rescue therapy. Increased risk of thromboembolism is associated with IVIG therapy in these doses.

Local Measures

In patients with limited disease, skin and mucous membrane lesions should be treated with topical corticosteroids. Complicating infection requires appropriate systemic and local antibiotic therapy.

Prognosis

The course tends to be chronic in most patients, though about one-third appear to experience remission. Infection is the most frequent cause of death, usually from *S aureus* septicemia.

Ahmed AR et al. Treatment of pemphigus vulgaris with rituximab and intravenous immune globulin. N Engl J Med. 2006 Oct 26;355(17):1772–9. [PMID: 17065638]

Dick SE. Pemphigus: a treatment update. Autoimmunity. 2006 Nov;39(7):591–9. [PMID: 17101503]

Bullous Pemphigoid

Many other autoimmune skin disorders are characterized by formation of bullae, or blisters. These include bullous pemphigoid, cicatricial pemphigoid, dermatitis herpetiformis, and pemphigoid gestationis.

Bullous pemphigoid is a relatively benign pruritic disease characterized by tense blisters in flexural areas, usually remitting in 5 or 6 years, with a course characterized by exacerbations and remissions (see photograph). Most affected persons are over the age of 60 (often in their 70s or 80s), and men are affected twice as frequently as women. The appearance of blisters may be preceded by urticarial or edematous lesions for months. Oral lesions are present in about one-third of affected persons. The disease may occur in various forms, including localized, vesicular, vegetating, erythematous, erythrodermic, and nodular.

The diagnosis is made by biopsy and direct immunofluorescence examination. Light microscopy shows a subepidermal blister. With direct immunofluorescence, IgG and C3 are found at the dermal-epidermal junction. If the patient has mild disease, ultrapotent corticosteroids may be adequate. Prednisone at a dosage of 0.75 mg/kg/d is often used to achieve rapid control of more widespread disease. Although slower in onset of action, tetracycline or erythromycin, 500 mg three times daily, alone or combined with nicotinamide—*not nicotinic acid or niacin!*—(up to 1.5 g/d), if tolerated, may control the disease in patients who cannot use corticosteroids or may allow decreasing or eliminating corticosteroids after control is achieved. Dapsone is particularly effective in mucous membrane pemphigoid. If these drugs are not effective, methotrexate, 5–25 mg weekly, or azathioprine, 50 mg one to three times daily, may be used as steroid-sparing agents. Mycophenolate mofetil (1 g twice daily) may be used in refractory cases.

Warts

Essentials of Diagnosis

- Verrucous papules anywhere on the skin or mucous membranes, usually no larger than 1 cm in diameter.
- Prolonged incubation period (average 2–18 months). Spontaneous "cures" are frequent (50% at 2 years for common warts).
- "Recurrences" (new lesions) are frequent.

General Considerations

Warts are caused by human papillomaviruses (HPVs). Typing of HPV lesions is NOT a part of standard medical evaluation except in the case of genital dysplasia. Genital HPV types are divided into low-risk and high-risk depending on the likelihood of their association with cervical and anal cancer.

Clinical Findings

There are usually no symptoms. Tenderness on pressure occurs with plantar warts; itching occurs with anogenital warts (Plate 35); (see photograph). Flat warts are most evident under oblique illumination. Periungual warts may be dry, fissured, and hyperkeratotic and may resemble hangnails or other nonspecific changes. Plantar warts resemble plantar corns or calluses.

Plate 35.

Condylomata acuminata, or genital warts, of the anal region due to human papillomavirus. (Public Health Image Library, CDC.)

Perianal condylomata acuminata. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Differential Diagnosis

Some warty-looking lesions are actually hypertrophic actinic keratoses or squamous cell carcinomas (see photograph). Some genital warty lesions may be due to secondary syphilis (condylomata lata). The lesions of molluscum contagiosum are pearly with a central dell (see photograph). In AIDS, wart-like lesions may be caused by varicella zoster virus.

Prevention

Administration of a vaccine against certain genital HPV types can prevent infection with these wart types and reduce cervical dysplasia. It is recommended for teenage and young adult women (see Chapter 1: Disease Prevention & Health Promotion).

Treatment

Treatment is aimed at inducing "wart-free" intervals for as long as possible without scarring, since no treatment can guarantee a remission or prevent recurrences. In immunocompromised patients, the goal is even more modest, ie, to control the size and number of lesions present.

Removal

For common warts of the hands, patients are usually offered liquid nitrogen or keratolytic agents. The former may work in fewer treatments but requires office visits and is painful.

Liquid nitrogen

Liquid nitrogen is applied to achieve a thaw time of 20–45 seconds. Two freeze-thaw cycles are given every 2–4 weeks for several visits. Scarring will occur if it is used incorrectly. Liquid nitrogen may cause permanent depigmentation in pigmented individuals. Cryotherapy is first-line physician applied surgical treatment for condyloma acuminata.

Keratolytic agents and occlusion

Salicylic acid products may be used against common warts or plantar warts. They are applied, then occluded. Plantar warts may be treated by applying a 40% salicylic acid plaster (Mediplast) after paring. The plaster may be left on for 5–6 days, then removed, the lesion pared down, and another plaster applied. Although it may take weeks or months to eradicate the wart, the method is safe and effective with almost no side effects. Chronic occlusion alone with water-impermeable tape (duct tape, adhesive tape) for months may be effective.

Podophyllum resin

For genital warts, the purified active component of the podophyllum resin, podofilox, is applied by the patient twice daily 3 consecutive days a week for cycles of 4–6 weeks. It is less irritating and more effective than "physician-applied" podophyllum resin. After a single 4-week cycle, 45% of patients were wart-free; but of these, 60% relapsed at 6 weeks. Thus, multiple cycles of treatment are often necessary. Patients unable to obtain the take home podofilox may be treated by in the clinician's office by painting each wart carefully (protecting normal skin) every 2–3 weeks with 25% podophyllum resin (podophyllin) in compound tincture of benzoin. Pregnant patients should not be so treated. Podophyllin is ineffective for common warts and plantar warts.

Imiquimod

A 5% cream of this local interferon inducer has moderate activity in clearing external genital warts (EGWs). Treatment is once daily on 3 alternate days per week. Response may be slow, with patients who eventually cleared having responses at 8 weeks (44%) or 12 weeks (69%). There is a marked gender difference with respect to response, with 77% of women and 40% of men having complete clearing of their lesions. Once cleared, about 13% have recurrences in the short term.

In accidental exposure during pregnancy, there is less risk with imiquimod than with podophyllum resin (category B versus category X). Imiquimod is considerably more expensive than podophyllotoxin, but given the high rate of response in women and its safety, it appears to be the "patient-administered" treatment of choice for EGWs in women. In men, the more rapid response, lower cost, and similar efficacy make podophyllotoxin the initial treatment of choice, with imiquimod used for recurrences or refractory cases. Imiquimod has no demonstrated efficacy for—and should not be used to treat—plantar or common warts.

Operative removal

Plantar warts may be removed by blunt dissection. For hemostasis, trichloroacetic acid or Monsel solution on a tightly wound cotton-tipped applicator may be painted on the wound, or light electrocautery may be used. For genital warts, snip biopsy (scissors) removal followed by light electrocautery is more effective than cryotherapy, especially for patients with pedunculated or large lesions.

Laser therapy

The CO_2 laser can be effective for treating recurrent warts, periungual warts, plantar warts, and condylomata acuminata. It leaves open wounds that must fill in with granulation tissue over 4–6 weeks and is best reserved for warts resistant to all other modalities. Lasers with emissions of 585, 595, or 532 nm may also be used every 3–4 weeks to gradually ablate common or plantar warts. This is no more effective than cryotherapy in controlled trials. For genital warts, it has not been shown that laser therapy is more effective than electrosurgical removal.

Other agents

Bleomycin diluted to 1 unit/mL may be injected into common and plantar warts. It has been shown to have a high cure rate. It should be used with caution on digital warts because of the potential complications of Raynaud phenomenon, nail loss, and terminal digital necrosis.

Immunotherapy

Squaric acid dibutylester may be effective. It is applied in a concentration of 0.2–2% directly to the warts from once weekly to five times weekly to induce a mild contact dermatitis. Between 60% and 80% of warts clear over 10–20 weeks. Injection of *Candida* antigen starting at 1:50 dilution and repeated every 3–4 weeks may be similarly effective in stimulating immunologic regression of common and plantar warts.

Physical Modalities

Soaking warts in hot (42.2 °C) water for 10–30 minutes daily for 6 weeks has resulted in involution in some cases.

Prognosis

There is a striking tendency to the development of new lesions. Warts may disappear spontaneously or may be unresponsive to treatment.

Callosities & Corns of Feet or Toes

Callosities and corns are caused by pressure and friction due to faulty weight-bearing, orthopedic deformities, improperly fitting shoes, or neuropathies.

Tenderness on pressure and "after-pain" are the only symptoms. The hyperkeratotic well-localized overgrowths always occur at pressure points. Dermatoglyphics (fingerprint lines) are preserved over the surface (not so in warts). When the surface is shaved with a 15 blade, a glassy core is found (which differentiates them from plantar warts, which have multiple capillary bleeding points or black dots when pared).

Treatment consists of correcting mechanical abnormalities that cause friction and pressure. Callosities may be removed by careful paring of the callus after a warm water soak or with keratolytic agents as found in various brands of corn pads.

Plantar hyperkeratosis of the heels can be treated successfully by using 20% urea (Ureacin 20) or 12% lactic acid (Lac-Hydrin) or combinations nightly and a pumice stone after soaking in water.

Callosities on diabetic feet, especially in the setting of hyposensate neuropathy, can be a major problem and the value of early podiatric management to prevent complications is very important.

Molluscum Contagiosum

Molluscum contagiosum, caused by a poxvirus, presents as single or multiple dome-shaped, waxy papules 2–5 mm in diameter that are umbilicated (Plate 36); (see photograph). Lesions at first are firm, solid, and flesh-colored but upon reaching maturity become soft, whitish, or pearly gray and may suppurate. The principal sites of involvement are the face, lower abdomen, and genitals.

Plate 36.

Molluscum contagiosum legion on the back. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

The lesions are autoinoculable and spread by wet skin-to-skin contact. In sexually active individuals, they may be confined to the penis, pubis, and inner thighs and are considered a sexually transmitted infection.

Molluscum contagiosum is common in patients with AIDS, usually with a helper T cell count < 100/mcL. Extensive lesions tend to develop over the face and neck as well as in the genital area.

The diagnosis is easily established in most instances because of the distinctive central umbilication of the dome-shaped lesion. The best treatment is by curettage or applications of liquid nitrogen as for warts—but more briefly. When lesions are frozen, the central umbilication often becomes more apparent. Light electrosurgery with a fine needle is also effective. It has been estimated that individual lesions persist for about 2 months. They are difficult to eradicate in patients with AIDS unless immunity improves. However, in AIDS, with highly effective anti-retroviral treatment molluscum does not need to be treated because they usually spontaneously clear.

Basal Cell Carcinoma

Essentials of Diagnosis

- Pearly papule, erythematous patch > 6 mm, or nonhealing ulcer, in sun exposed areas (face, trunk, lower legs).
- History of bleeding.
- Fair-skinned person with a history of sun exposure (often intense, intermittent).

General Considerations

Basal cell carcinomas are the most common form of cancer. They occur on sun-exposed skin in otherwise normal fair-skinned individuals; ultraviolet light is the cause. The most common presentation is a papule or nodule that may have a central scab or erosion (Plate 37); (see photograph). Occasionally the nodules have stippled pigment (pigmented basal cell carcinoma). Intradermal nevi without pigment on the face of older white individuals may resemble basal cell carcinomas. Basal cell carcinomas grow slowly, attaining a size of 1–2 cm or more in diameter, usually only after years of growth. There is a waxy, "pearly" appearance, with telangiectatic vessels easily visible (Plate 38); (see photograph). It is the pearly or translucent quality of these lesions that is most diagnostic, a feature best appreciated if the skin is stretched (see photograph). These are hypopigmented, somewhat thickened plaques. On the back and chest, basal cell carcinomas appear as reddish, somewhat shiny, scaly patches.

Fig.

Basal cell carcinoma located on the inferomedial eyelid. It is the pearly or translucent quality of these lesions that is most diagnostic. (Courtesy of S Goldstein.)

Clinicians should examine the whole skin routinely, looking for bumps, patches, and scabbed lesions. When examining the face, look at the eyelid margins and medial canthi, the nose and alar folds, the lips, and then around and behind the ears. While metastases almost never occur, therapy of basal cell carcinomas may cause significant cosmetic deformity in these areas, particularly for inadequately treated or recurrent lesions.

Treatment

Lesions suspected to be basal cell carcinomas should be biopsied, by shave or punch biopsy (see illustration); (see illustration). Therapy is then aimed at eradication with minimal cosmetic deformity, often by excision and suturing with recurrence rates of 5% or less. The technique of three cycles of curettage and electrodesiccation depends on the skill of the operator and is not recommended for head and neck lesions. After 4–6 weeks of healing, it leaves a broad, hypopigmented, at times hypertrophic scar. Radiotherapy is effective and sometimes appropriate for older individuals (over 65), but recurrent tumors after radiation therapy are more difficult to treat and may be more aggressive. Radiation therapy is the most expensive method to treat basal cell carcinoma and should only be used if other treatment options are not appropriate. Mohs surgery—removal of the tumor followed by immediate frozen section histopathologic examination of margins with subsequent reexcision of tumor-positive areas and final closure of the defect—gives the highest cure rates (98%) and results in least tissue loss. It is appropriate therapy for tumors of the eyelids, nasolabial folds, canthi, external ear, and temple; for recurrent lesions; or where tissue sparing is needed for cosmesis. Since up to half of patients with a basal cell carcinoma will develop a second lesion, patients with basal cell carcinomas must be monitored to detect new or recurrent lesions.

Squamous Cell Carcinoma

Essentials of Diagnosis

- Nonhealing ulcer or warty nodule.
- Skin damage due to long-term sun exposure.
- Common in fair-skinned organ transplant recipients.

Squamous cell carcinoma usually occurs subsequent to prolonged sun exposure on exposed parts in fair-skinned individuals who sunburn easily and tan poorly. It may arise from an actinic keratosis. The lesions appear as small red, conical, hard nodules that occasionally ulcerate (Plate 39); (see photograph); (see photograph). The frequency of metastasis is not precisely known, though metastatic spread is said to be less likely with squamous cell carcinoma arising out of actinic keratoses than with those that arise de novo. In actinically induced squamous cell cancers, rates of metastasis are estimated from retrospective studies to be 3–7%. Squamous cell carcinomas of the lip, oral cavity, tongue, and genitalia have much higher rates of metastasis and require special management.

Plate 39.
Squamous cell carcinoma. (Used, with permission, from Berger TG, Dept. Dermatology, UCSF.)

Fig.

Examination of the skin and therapy are essentially the same as for basal cell carcinoma. The preferred treatment of squamous cell carcinoma is excision. Electrodesiccation and curettage and x-ray radiation may be used for some lesions, and fresh tissue microscopically controlled excision (Mohs) is recommended for high-risk lesions (lips, temples, ears, nose) and for recurrent tumors. Follow-up for squamous cell carcinoma must be more frequent and thorough than for basal cell carcinoma, starting at every 3 months, with careful examination of lymph nodes. In addition, palpation of the lips is essential to detect hard or indurated areas that represent early squamous cell carcinoma. All such cases must be biopsied. Multiple squamous cell carcinomas are very common on the sun-exposed skin of organ transplant patients. The intensity of immunosuppression, not the use of any particular immunosuppressive agent, is the primary risk factor in determining the development of skin cancer after transplant. The tumors begin to appear after 5 years of immunosuppression. Regular dermatologic evaluation in at-risk organ transplant recipients is recommended. Biologic behavior of skin cancer in organ transplant recipients may be aggressive, and careful management is required. Other forms of immunosuppression such as chronic lymphocytic leukemia, HIV/AIDS, and chronic iatrogenic immunosuppression may also increase skin cancer risk and be associated with more aggressive skin cancer behavior.

Zafar SY et al. Malignancy after solid organ transplantation: an overview. Oncologist. 2008 Jul;13(7):769–78. [PMID: 18614590]

Lichen Planus

Essentials of Diagnosis

- Pruritic, violaceous, flat-topped papules with fine white streaks and symmetric distribution.
- Lacy lesions of the buccal mucosa.
- Commonly seen along linear scratch marks (Koebner phenomenon) on anterior wrists, penis, legs.
- Histopathologic examination is diagnostic.

General Considerations

Lichen planus is an inflammatory pruritic disease of the skin and mucous membranes characterized by distinctive papules with a predilection for the flexor surfaces and trunk. The three cardinal findings are typical skin lesions, mucosal lesions, and histopathologic features of band-like infiltration of lymphocytes in the upper dermis. The most common drugs causing lichen planus-like reactions include sulfonamides, tetracycline, quinidine, NSAIDs, and hydrochlorothiazide. Hepatitis C infection is found with greater frequency in lichen planus patients than in controls. Allergy to mercury amalgams can trigger oral lesions identical to lichen planus.

Clinical Findings

Itching is mild to severe. The lesions are violaceous, flat-topped, angulated papules, up to 1 cm in diameter, discrete or in clusters, with very fine white streaks (Wickham striae) on the flexor surfaces of the wrists and on the penis, lips, tongue as well as buccal, vaginal, and anorectal mucous membranes (Plate 40); (see photograph); (see photograph). The papules may become bullous or eroded. The disease may be generalized. Mucous membrane lesions have a lacy white network overlying them that may be confused with leukoplakia. The Koebner phenomenon (appearance of lesions in areas of trauma) may be seen.

Plate 40.
Lichen planus. (Used, with permission, from Berger TG, Dept. Dermatology, UCSF.)

Fig.

Papular lesion of lichen planus on the flexor surface of the wrist. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Fig.

Hypertrophic papular lesions of lichen planus of the ankle. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

A special form of lichen planus is the erosive or ulcerative variety, a major problem in the mouth or genitalia. Squamous cell carcinoma develops in 5% of patients with erosive oral or genital lichen planus.

Differential Diagnosis

Lichen planus must be distinguished from similar lesions produced by medications (see above) and other papular lesions such as psoriasis, lichen simplex chronicus (see photograph), graft-versus-host disease, and syphilis (see photograph). Lichen planus on the mucous membranes must be differentiated from leukoplakia. Erosive oral lesions require biopsy and often direct immunofluorescence for diagnosis since lichen planus may simulate other erosive diseases.

Fig.

Lichen simplex chronicus (dark raised bumps on a black female). (Courtesy of K Zipperstein.)

Treatment

Topical Therapy

Superpotent topical corticosteroids applied twice daily are most helpful for localized disease in nonflexural areas. Alternatively, high-potency corticosteroid cream or ointment may be used nightly under thin pliable plastic film.

Topical tacrolimus appears effective in oral and vaginal erosive lichen planus, but long-term therapy is required to prevent relapse. If tacrolimus is used, lesions must be observed carefully for development of cancer. Since absorption can occur through mucous membranes, serum tacrolimus levels should be checked at least once if widespread mucosal application (> 5–10 cm^2) is used. If the erosive oral lichen planus lesions are adjacent to a mercury containing amalgam, removal of the amalgam may result in clearing of the erosions.

Systemic Therapy

Corticosteroids (see Chapter 26: Endocrine Disorders) may be required in severe cases or in circumstances where the most rapid response to treatment is desired. Unfortunately, relapse almost always occurs as the corticosteroids are tapered, making systemic corticosteroid therapy an impractical option for the management of chronic lichen planus. NB-UVB, bath PUVA, oral PUVA, and the combination of an oral retinoid plus PUVA (re-PUVA) are all forms of phototherapy that can improve lichen planus. Hydroxychloroquine, 200 mg orally twice daily, can also be effective in mucosal lichen planus.

Prognosis

Lichen planus is a benign disease, but it may persist for months or years and may be recurrent. Hypertrophic lichen planus and oral lesions tend to be especially persistent, and neoplastic degeneration has been described in chronically eroded lesions.

Kaposi Sarcoma

General Considerations

Before 1980 in the United States, this rare malignant skin lesion was seen mostly in elderly men, had a chronic clinical course, and was rarely fatal. Kaposi sarcoma occurs endemically in an often aggressive form in young black men of equatorial Africa, but it is rare in American blacks. Kaposi sarcoma continues to occur largely in homosexual men with HIV infection as an AIDS-defining illness. Kaposi sarcoma may complicate immunosuppressive therapy, and stopping the immunosuppression may result in improvement. Human herpes virus 8 (HHV-8), or Kaposi sarcoma-associated herpes virus (KSHV), is universally present in all forms of Kaposi sarcoma.

Red or purple plaques or nodules on cutaneous or mucosal surfaces are characteristic (Plate 41) (see photograph); (see photograph). Marked edema may occur with few or no skin lesions. Kaposi sarcoma commonly involves the gastrointestinal tract and can be screened for by fecal occult blood testing. In asymptomatic patients, these lesions are not sought or treated. Pulmonary Kaposi sarcoma can present with shortness of breath, cough, hemoptysis, or chest pain; it may be asymptomatic, appearing only on chest radiograph. Bronchoscopy may be indicated. The incidence of AIDS-associated Kaposi sarcoma is diminishing.

Fig.

Kaposi's sarcoma. Characteristic dark purple macules and nodular plaques.

Treatment

For Kaposi sarcoma in the elderly, palliative local therapy with intralesional chemotherapy or radiation is usually all that is required. In the setting of iatrogenic immunosuppression, the treatment of Kaposi sarcoma is primarily reduction of doses of immunosuppressive medications. In AIDS-associated Kaposi sarcoma, the patient should first be given effective anti-HIV antiretrovirals because in most cases this treatment alone is associated with improvement. Other therapeutic options include cryotherapy or intralesional vinblastine (0.1–0.5 mg/mL) for cosmetically objectionable lesions; radiation therapy for accessible and space-occupying lesions; and laser surgery for certain intraoral and pharyngeal lesions. Systemic therapy is indicated in patients with rapidly progressive skin disease (more than ten new lesions per month), with edema or pain, and with symptomatic visceral disease or pulmonary disease. Liposomal doxorubicin is highly effective in controlling these cases and has considerably less toxicity—and greater efficacy—than anthracycline monotherapy or combination chemotherapeutic regimens. -Interferon may also be used. Paclitaxel and other taxanes can be effective even in patients who do not respond to anthracycline treatment. Col-3, a tetracycline derivative, has produced responses in refractory cases.

Pruritus: Introduction

Pruritus is a disagreeable sensation that provokes a desire to scratch. It is modulated by central factors, including anxiety, depression, and amphetamine and cocaine use. Many cases of pruritus are not mediated by histamine.

Dry skin is the first cause of itch that should be sought, since it is common and easily treated. Other causes include scabies, atopic dermatitis, insect bites, pediculosis, contact dermatitis, drug reactions, urticaria, psoriasis, lichen planus, lichen simplex chronicus, and fiberglass dermatitis.

Persistent pruritus not explained by cutaneous disease or association with a primary skin eruption should prompt a staged workup for systemic causes. Perhaps the most common cause of pruritus associated with systemic disease is uremia in conjunction with hemodialysis. Both this condition and the pruritus of liver disease may be helped by phototherapy with ultraviolet B or PUVA. Naltrexone and nalmefene have been shown to relieve the pruritus of liver disease. Naltrexone is not effective in pruritus associated with advanced chronic kidney disease, but gabapentin may be effective. Endocrine disorders such as hypothyroidism or hyperthyroidism, psychiatric disturbances, lymphoma, leukemia, and other internal malignant disorders, iron deficiency anemia, and certain neurologic disorders may also cause pruritus. Antihistamines reduce pruritus only by their sedating effect (except in urticaria). Nonsedating, second-generation antihistamines are of limited value in nonurticarial pruritus.

Prognosis

Elimination of external factors and irritating agents may give complete relief. Pruritus accompanying a specific skin disease will subside when the skin disease is controlled. Pruritus accompanying serious internal disease may not respond to any type of therapy.

Anogenital Pruritus

Essentials of Diagnosis

- Itching, chiefly nocturnal, of the anogenital area.
- Examination is highly variable, ranging from no skin findings to excoriations and inflammation of any degree, including lichenification.

General Considerations

Anogenital pruritus may be due to intertrigo, psoriasis, lichen simplex chronicus, or seborrheic or contact dermatitis (from soaps, colognes, douches, contraceptives, and perhaps scented toilet tissue), or it may be due to irritating secretions, as in diarrhea, leukorrhea, or trichomoniasis, or to local disease (candidiasis, dermatophytosis, erythrasma), and at times oxyuriasis (pinworms). Lichen sclerosus may at times be the cause. Erythrasma is easily diagnosed by demonstration of coral-red fluorescence with Wood's light; it is easily cured with erythromycin orally or topically (Plate 42).

Plate 42.

Erythrasma of the axilla. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

In pruritus ani, hemorrhoids are often found, and leakage of mucus and bacteria from the distal rectum onto the perianal skin may be important in cases in which no other skin abnormality is found.

Many women experience pruritus vulvae. Pruritus vulvae does not usually involve the anal area, though anal itching may spread to the vulva. In men, pruritus of the scrotum is most commonly seen in the absence of pruritus ani. Up to one-third of causes of anogenital pruritus may be due to nerve impingements of the lumbosacral spine, so referral for evaluation of lumbosacral spine disease is appropriate if no skin disorder is identified, and topical therapy is ineffective. Squamous cell carcinoma of the anus and extramammary Paget disease are rare causes of genital pruritus.

Clinical Findings

Symptoms and Signs

The only symptom is itching. Physical findings are usually not present, but there may be erythema, fissuring, maceration, lichenification, excoriations, or changes suggestive of candidiasis or tinea.

Laboratory Findings

Urinalysis and blood glucose testing may lead to a diagnosis of diabetes mellitus. Microscopic examination or culture of tissue scrapings may reveal yeasts or fungi. Stool examination may show pinworms. Radiologic studies may demonstrate spinal cord disease.

Differential Diagnosis

The etiologic differential diagnosis consists of *Candida* infection, parasitosis, local irritation from contactants or irritants, nerve impingement and other primary skin disorders of the genital area such as psoriasis, seborrhea, intertrigo, or lichen sclerosus et atrophicus (see photograph).

Fig.

Lichen sclerosis et atrophicus: buttocks. (Courtesy of K Zipperstein.)

Prevention

Instruct the patient in proper anogenital hygiene after treating systemic or local conditions. If appropriate, physical therapy and exercises to support the lower spine are recommended.

Treatment

General Measures

Treating constipation, preferably with high-fiber management (psyllium), may help. Instruct the patient to use very soft or moistened tissue or cotton after bowel movements and to clean the perianal area thoroughly with cool water if possible. Women should use similar precautions after urinating.

Local Measures

Pramoxine cream or lotion or hydrocortisone-pramoxine (Pramosone), 1% or 2.5% cream, lotion, or ointment, is helpful in managing pruritus in the anogenital area. The ointment or cream should be applied after a bowel movement. Topical doxepin cream 5% is similarly effective, but it may be sedating. The use of strong corticosteroids on the scrotum may lead to persistent severe burning upon withdrawal of the drug. Underclothing should be changed daily. Balneol Perianal Cleansing Lotion or Tucks premoistened pads, ointment, or cream may be very useful for pruritus ani. About one-third of patients with scrotal or anal pruritus will respond to capsaicin 0.006%. Treatment for underlying spinal neurologic disease may be required.

Prognosis

Although benign, anogenital pruritus is often persistent and recurrent.

Siddiqi S et al. Pruritus ani. Ann R Coll Surg Engl. 2008 Sep;90(6):457–63. [PMID: 18765023]

Scabies

Essentials of Diagnosis

- Generalized very severe itching.
- Pruritic burrows, vesicles and pustules, especially on finger webs and in wrist creases.
- Mites, ova, and brown dots of feces visible microscopically.
- Red papules or nodules on the scrotum and on the penile glans and shaft are pathognomonic.

General Considerations

Scabies is caused by infestation with *Sarcoptes scabiei.* The infestation usually spares the head and neck (though even these areas may be involved in infants, in the elderly, and in patients with AIDS). Scabies is usually acquired by sleeping with or in the bedding of an infested individual or by other close contact. The entire household may be affected. Hospital-associated scabies is increasingly common, primarily in long-term care facilities. Index patients are usually elderly and immunosuppressed. When these patients are hospitalized, hospital-based epidemics can occur. These epidemics are difficult to eradicate since many health care workers become infected and spread the infestation to other patients.

Clinical Findings

Symptoms and Signs

Itching is almost always present and can be quite severe. The lesions consist of more or less generalized excoriations with small pruritic vesicles, pustules, and "burrows" in the web spaces and on the heels of the palms, wrists, elbows, around the axillae, and on the breasts of women (Plate 43); (see photograph); (see photograph). The feet are a good place to identify burrows, since they may have been scratched off in other locations. The burrow appears as a short irregular mark, 2–3 mm long and the width of a hair. Characteristic nodular lesions may occur on the scrotum or penis and along the posterior axillary line (see photograph).

Plate 43.

Scabies. (Used, with permission, from Berger TG, Dept. Dermatology, UCSF.)

Fig.

Multiple burrows and papules are present on the finger webs. (Courtesy of A Hoke.)

Fig.

Nodular scabies. Multiple nodules are present on the penile shaft. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Laboratory Findings

The diagnosis should be confirmed by microscopic demonstration of the organism, ova, or feces in a mounted specimen (see micrograph), examined with tap water. Best results are obtained when multiple lesions are scraped, choosing the best unexcoriated lesions from interdigital webs, wrists, elbows, or feet. A No. 15 blade is used to scrape each lesion until it is flat. Pinpoint bleeding may result from the scraping. Patients with crusted/hyperkeratotic scabies must be evaluated for immunosuppression (especially HIV and HTLV-1 infections), if no iatrogenic cause of immunosuppression is present.

Fig.

Skin scrapings of burrows disclose large eggs and numerous fecal pellets. (Courtesy of A Hoke.)

Differential Diagnosis

Scabies must be distinguished from the various forms of pediculosis, from bedbug and flea bites, and from other causes of pruritus.

Treatment & Prognosis

Treatment is aimed at killing scabies mites and controlling the dermatitis, which can persist for months after effective eradication of the mites. Bedding and clothing should be laundered or cleaned or set aside for 14 days in plastic bags. High heat (60 °C) is required to kill the mites and ova (see photograph). Unless treatment is aimed at all infected persons in a family or institutionalized group, reinfestations will probably occur.

Fig.

Pyoderma of the penis is highly suggestive of scabies.

(Courtesy of A Hoke.)

Permethrin 5% cream is highly effective and safe in the management of scabies. Treatment consists of a single application for 8–12 hours, repeated in 1 week.

Pregnant patients should be treated only if they have documented scabies themselves. Permethrin 5% cream once for 12 hours—or 5% or 6% sulfur in petrolatum applied nightly for 3 nights from the collarbones down—may be used.

Patients will continue to itch for several weeks after treatment. Use of triamcinolone 0.1% cream will help resolve the dermatitis. Scabies in nursing home patients, institutionalized or mentally impaired (especially Down syndrome) patients, and AIDS patients may be much more difficult to treat.

Most failures in normal persons are related to incorrect use or incomplete treatment of the housing unit. In these cases, repeat treatment with permethrin once weekly for 2 weeks, with reeducation regarding the method and extent of application, is suggested. In immunocompetent individuals, ivermectin in a dose of 200 mcg/kg is effective in about 75% of cases with a single dose and 95% of cases with two doses 2 weeks apart. In immunosuppressed hosts and those with crusted (hyperkeratotic) scabies, multiple doses of ivermectin (every 2 weeks for two or three doses) plus topical therapy with permethrin once weekly may be effective when topical treatment and oral therapy alone fail. Oral ivermectin can be very beneficial in mass treatment to eradicate infections in institutions or villages.

If secondary pyoderma is present, it is treated with systemic antibiotics. In areas where nephritogenic streptococcal strains are prevalent, infestation with scabies or exposure to scabies-infested dogs may be followed by acute post-streptococcal glomerulonephritis.

Persistent pruritic postscabietic papules may be treated with mid- to high-potency corticosteroids or with intralesional triamcinolone acetonide (2.5–5 mg/mL).

Pediculosis

Essentials of Diagnosis

- Pruritus with excoriation.
- Nits on hair shafts; lice on skin or clothes.
- Occasionally, sky-blue macules (maculae ceruleae) on the inner thighs or lower abdomen in pubic louse infestation.

General Considerations

Pediculosis is a parasitic infestation of the skin of the scalp, trunk, or pubic areas. Body lice usually occur among people who live in overcrowded dwellings with inadequate hygiene facilities. Pubic lice may be sexually transmitted. Head lice may be transmitted by shared use of hats or combs. Adults contacting children with head lice frequently acquire the infestation.

There are three different varieties: (1) pediculosis pubis, caused by *Phthirus pubis* (pubic louse, "crabs"); (2) pediculosis corporis, caused by *Pediculus humanus* var *corporis* (body louse); and (3) pediculosis capitis, caused by *Pediculus humanus* var *capitis* (head louse).

Head and body lice are similar in appearance and are 3–4 mm long. The body louse can seldom be found on the body, because the insect comes onto the skin only to feed and must be looked for in the seams of the clothing. Trench fever, relapsing fever, and typhus are transmitted by the body louse in countries where those diseases are endemic.

Clinical Findings

Itching may be very intense in body louse infestations, and scratching may result in deep excoriations, especially over the upper shoulders, posterior flanks, and neck. In some cases, only itching is present, with few excoriations seen. Pyoderma may be the presenting sign. Head lice can be found on the scalp or may be manifested as small nits resembling pussy willow buds on the scalp hairs close to the skin (see photograph); (see photograph). They are easiest to see above the ears and at the nape of the neck. Pubic louse infestations are occasionally generalized, particularly in hairy individuals; the lice may even be found on the eyelashes and in the scalp.

Fig.

Pediculosis capitis. Myriads of nits are attached to hair on occipital scalp. Erythematous, excoriated patches are noted. (Courtesy of A Hoke.)

Fig.

Pediculosis capitis. Upper hair shows nonviable nit (empty with operculum raised); lower hair shows intact, viable, unhatched nit (embryo with eye spot and claws). (Courtesy of Professor David Taplin and Terri Meinking. Reproduced, with permission, from Curr Concepts Skin Dis 1989;10:6.)

Differential Diagnosis

Head louse infestation must be distinguished from seborrheic dermatitis, body louse infestation from scabies and bedbug bites, and pubic louse infestation from anogenital pruritus and eczema.

Treatment

Body lice are treated by disposing of the infested clothing and addressing the patient's social situation. For pubic lice, permethrin rinse 1% for 10 minutes and permethrin cream 5% applied for 8 hours are effective. Sexual contacts should be treated. Clothes and bedclothes should be washed and dried at high temperature if possible.

Permethrin 1% cream rinse (Nix) is a topical over-the-counter pediculicide and ovicide and is the treatment of choice for head lice. It is applied to the scalp and hair and left on for 8 hours before being rinsed off. Permethrin resistance of head lice is common. Malathion lotion 1% (Ovide) is very effective, but it is highly volatile and flammable, so application must be done in a well-ventilated room or out of doors. For involvement of eyelashes, petrolatum is applied thickly twice daily for 8 days, and remaining nits are then plucked off.

Leone PA. Scabies and pediculosis pubis: an update of treatment regimens and general review. Clin Infect Dis. 2007 Apr 1;44(Suppl 3):S153–9. [PMID: 17342668]

Skin Lesions Due to Other Arthropods

Essentials of Diagnosis

- Localized rash with pruritus.
- Furuncle-like lesions containing live arthropods.
- Tender erythematous patches that migrate ("larva migrans").
- Generalized urticaria or erythema multiforme in some patients.

General Considerations

Some arthropods (eg, mosquitoes and biting flies) are readily detected as they bite. Many others are not, eg, because they are too small, because there is no immediate reaction, or because they bite during sleep. Reactions are allergic and may be delayed for hours to days. Patients are most apt to consult a clinician when the lesions are multiple and pruritus is intense.

Many persons will react severely only to their earliest contacts with an arthropod, thus presenting pruritic lesions when traveling, moving into new quarters, etc. Body lice, fleas, bedbugs, and mosquitoes should be considered. Spiders are often incorrectly believed to be the source of bites; they rarely attack humans, though the brown spider *(Loxosceles laeta, Loxosceles reclusa)* may cause severe necrotic reactions and death due to intravascular hemolysis, and the black widow spider *(Latrodectus mactans)* may cause severe systemic symptoms and death. (See also Chapter 38: Poisoning.) The majority of patient-diagnosed, physician-diagnosed, and even published cases of brown recluse spider bites (or loxoscelism) are incorrect, especially if made in areas where these spiders are not endemic. Many of these lesions are actually due to CA-MRSA.

In addition to arthropod bites, the most common lesions are venomous stings (wasps, hornets, bees, ants, scorpions) or bites (centipedes), furuncle-like lesions due to fly maggots or sand fleas in the skin, and a linear creeping eruption due to a migrating larva.

Clinical Findings

The diagnosis may be difficult when the patient has not noticed the initial attack but suffers a delayed reaction. Individual bites are often in clusters and tend to occur either on exposed parts (eg, midges and gnats) or under clothing, especially around the waist or at flexures (eg, small mites or insects in bedding or clothing). The reaction is often delayed for 1–24 hours or more. Pruritus is almost always present and may be all but intolerable once the patient starts to scratch. Secondary infection may follow scratching. Urticarial wheals are common. Papules may become vesicular. The diagnosis is aided by searching for exposure to arthropods and by considering the patient's occupation and recent activities.

The principal arthropods are as follows:

1. **Fleas:** Fleas are bloodsucking ectoparasites that feed on dogs, cats, humans, and other species. Flea saliva produces papular urticaria in sensitized individuals. To break the life cycle of the flea, one must treat the home and pets, using quick-kill insecticides, residual insecticides, and a growth regulator.

2. **Bedbugs:** In crevices of beds or furniture; bites tend to occur in lines or clusters. Papular urticaria is a characteristic lesion of bedbug (*Cimex lectularius*) bites. Bedbugs are not restricted to any socioeconomic group and are a major health problem in some major metropolitan areas, especially in commercial and

residential hotels.

3. **Ticks:** Usually picked up by brushing against low vegetation.

4. **Chiggers or red bugs:** These are larvae of trombiculid mites. A few species confined to particular regions and locally recognized habitats (eg, berry patches, woodland edges, lawns, brush turkey mounds in Australia, poultry farms) attack humans, often around the waist, on the ankles, or in flexures, raising intensely itching erythematous papules after a delay of many hours. The red chiggers may sometimes be seen in the center of papules that have not yet been scratched (see photograph).

Fig.

Chigger bites after camping. If the lesion has not been scratched, close examination may reveal the red chigger. (Courtesy of S Goldstein.)

5. **Bird and rodent mites:** Larger than chiggers, bird mites infest birds and their nests. Bites are multiple anywhere on the body. Room air conditioning units may suck in bird mites and infest the inhabitants of the room. Rodent mites from mice or rats may cause similar effects. If the domicile has evidence of rodent activity, then

rodent mite dermatitis should be suspected, as the mites are rarely found. Pet rodents or birds may be infested with mites, maintaining the infestation..

6. **Mites in stored products:** These are white and almost invisible and infest products such as copra, vanilla pods, sugar, straw, cottonseeds, and cereals. Persons who handle these products may be attacked, especially on the hands and forearms and sometimes on the feet.

7. **Caterpillars of moths with urticating hairs:** The hairs are blown from cocoons or carried by emergent moths, causing severe and often seasonally recurrent outbreaks after mass emergence. The gypsy moth is a cause in the eastern United States.

8. **Tungiasis:** Tungiasis is due to the burrowing flea known as *Tunga penetrans* and is found in Africa, the West Indies, and South and Central America. The female burrows under the skin, sucks blood, swells to 0.5 cm, and then ejects her eggs onto the ground. Ulceration, lymphangitis, gangrene, and septicemia may result, in some cases with lethal effect. Simple surgical removal is usually performed.

Differential Diagnosis

Arthropods should be considered in the differential diagnosis of skin lesions showing any of the above symptoms.

Prevention

Arthropod infestations are best prevented by avoidance of contaminated areas, personal cleanliness, and disinfection of clothing, bedclothes, and furniture as indicated. Chiggers and mites can be repelled by permethrin applied to the head and clothing. (It is not necessary to remove clothing.) Bedbugs are no longer repelled by permethrin. Aggressive hygiene and removal of the infested occupant from the domicile may be required to eradicate bedbug infestation in a residence.

Treatment

Living arthropods should be removed carefully with tweezers after application of alcohol and preserved in alcohol for identification. In endemic Rocky Mountain spotted fever areas, ticks should not be removed with the bare fingers.

Corticosteroid lotions or creams are helpful. Topical antibiotics may be applied if secondary infection is suspected. Localized persistent lesions may be treated with intralesional corticosteroids.

Stings produced by many arthropods may be alleviated by applying papain powder (Adolph's Meat Tenderizer) mixed with water, or aluminum chloride hexahydrate (Xerac AC).

Extracts from venom sacs of bees, wasps, yellow jackets, and hornets are available for immunotherapy of patients at risk for anaphylaxis.

Erythema Nodosum

Essentials of Diagnosis

- Painful red nodules without ulceration on anterior aspects of legs.
- Slow regression over several weeks to resemble contusions.
- Women are predominantly affected by a ratio of 10:1 over men.
- Some cases associated with infection or drug exposure.

General Considerations

Erythema nodosum is a symptom complex characterized by tender, erythematous nodules that appear most commonly on the extensor surfaces of the lower legs. It usually lasts about 6 weeks and may recur. The disease may be associated with various infections—streptococcosis, primary coccidioidomycosis, other deep fungal infections, tuberculosis, *Yersinia pseudotuberculosis* and *Yersinia enterocolitica* infection, or syphilis. It may accompany sarcoidosis, Behçet disease, and inflammatory bowel disease. Erythema nodosum may be associated with pregnancy or with use of oral contraceptives or other medication.

Clinical Findings

Symptoms and Signs

The subcutaneous swellings are exquisitely tender and may be preceded by fever, malaise, and arthralgia. They are most often located on the anterior surfaces of the legs below the knees but may occur on the arms, trunk, and face (see photograph). The lesions, 1–10 cm in diameter, are at first pink to red; with regression, all the various hues seen in a contusion can be observed (Plate 44).

Fig.

Erythema nodosum. Nodules on the legs are usually very tender. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Plate 44.

Erythema nodosum. (Used, with permission, from Berger TG, Dept. Dermatology, UCSF.)

Laboratory Findings

Evaluation of patients presenting with acute erythema nodosum should include a careful history (including drug exposures) and physical examination for prior upper respiratory infection or diarrheal illness, symptoms of any deep fungal infection endemic to the area, a chest radiograph, a PPD, and two consecutive ASO/DNAseB titers at 2- to 4-week intervals. If no underlying cause is found, only a small percentage of patients will go on to develop a significant underlying illness (usually sarcoidosis) over the next year.

Differential Diagnosis

Erythema induratum from tuberculosis is seen on the posterior surfaces of the legs and may ulcerate. Lupus panniculitis presents as tender nodules on the buttocks and posterior arms that heal with depressed scars (see photograph). In polyarteritis nodosa, the subcutaneous nodules are often associated with a fixed livedo. In the late stages, erythema nodosum must be distinguished from simple bruises and contusions.

Fig.

Lupus panniculitis profundum. (Courtesy of K Zipperstein.)

Treatment

First, the underlying cause should be identified and treated. Primary therapy is with NSAIDs in usual doses. Saturated solution of potassium iodide, 5–15 drops three times daily, results in prompt involution in many cases. Complete bed rest may be advisable if the lesions are painful. Systemic therapy directed against the lesions themselves may include corticosteroid therapy (see Chapter 26: Endocrine Disorders) unless contraindicated by associated infection.

Prognosis

The lesions usually disappear after about 6 weeks, but they may recur.

Campen RB et al. Case records of the Massachusetts General Hospital. Case 25-2006. A 41-year-old woman with painful subcutaneous nodules. N Engl J Med. 2006 Aug 17;355(7):714–22. [PMID: 16914708]

Schwartz RA et al. Erythema nodosum: a sign of systemic disease. Am Fam Physician. 2007 Mar 1;75(5):695–700. [PMID: 17375516]

Furunculosis (Boils) & Carbuncles

Essentials of Diagnosis

- Extremely painful inflammatory swelling based on a hair follicle that forms an abscess.
- Predisposing condition (diabetes mellitus, HIV disease, injection drug use) sometimes present.
- Coagulase-positive *Staphylococcus aureus* is the causative organism.

General Considerations

A furuncle (boil) is a deep-seated infection (abscess) caused by *S aureus* and involving the entire hair follicle and adjacent subcutaneous tissue. The most common sites of occurrence are the hairy parts exposed to irritation and friction, pressure, or moisture. Because the lesions are autoinoculable, they are often multiple. Diabetes mellitus (especially if using insulin injections), injection drug use, allergy injections, and HIV disease all increase the risk of staphylococcal infections by increasing the rate of carriage. Certain other exposures including hospitalization, athletic teams, prisons, military service, and homelessness may also increase the risk of infection.

A carbuncle consists of several furuncles developing in adjoining hair follicles and coalescing to form a conglomerate, deeply situated mass with multiple drainage points.

Clinical Findings

Symptoms and Signs

Pain and tenderness may be prominent. The abscess is either rounded or conical. It gradually enlarges, becomes fluctuant, and then softens and opens spontaneously after a few days to 1–2 weeks to discharge a core of necrotic tissue and pus (see photograph). The inflammation occasionally subsides before necrosis occurs. Infection of the soft tissue around the nails (paronychia) may be due to staphylococci when it is acute or *Candida* when chronic (see photograph).

Fig.

A furuncle is an abscess of a hair follicle. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Fig.

Chronic paronychia. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Laboratory Findings

There may be slight leukocytosis, but a white blood cell count is rarely required. Pus should be cultured to rule out MRSA or other bacteria. Culture of the anterior nares may identify chronic staphylococcal carriage in cases of recurrent cutaneous infection.

Differential Diagnosis

The most common entity in the differential is an inflamed epidermal inclusion cyst that suddenly becomes red, tender, and expands greatly in size over one to a few days (see photograph). The history of a prior cyst in the same location, the presence of a clearly visible cyst orifice, and the extrusion of malodorous cheesy rather than purulent material helps in the diagnosis. Tinea profunda (deep dermatophyte infection of the hair follicle) may simulate recurrent furunculosis. Furuncle is also to be distinguished from deep mycotic infections such as sporotrichosis; from other bacterial infections such as anthrax and tularemia (rare); from atypical mycobacterial infections; and from acne cysts (see photograph). Hidradenitis suppurativa presents with recurrent tender sterile abscesses in the axillae and groin, on the buttocks, or below the breasts (see photograph). The presence of old scars or sinus tracts plus negative cultures suggests this diagnosis.

Fig.

Inflamed epidermal inclusion cyst. (Courtesy of K Zipperstein.)

Fig.

Chronic hidradenitis suppurative of buttocks and perianal skin. Scarring, sinus tracts, and abscess formation are present–all signs of chronic recurrent disease. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Complications

Serious and sometimes fatal complications of staphylococcal infection such as septicemia can occur.

Prevention

Identifying and eliminating the source of infection is critical to prevent recurrences after treatment. The source individual may have chronic dermatitis or be an asymptomatic carrier. Local measures such as meticulous handwashing; no sharing of towels and clothing; aggressive scrubbing of showers, bathrooms and surfaces with bleach; bleach baths ($^1/_2$ to 1 cup per 20 liters of bathwater for 15 minutes 3–5 times weekly) and isolation of infected patients who reside in institutions to prevent spread are all effective measures.

Treatment

Specific Measures

Incision and drainage is recommended for all loculated suppurations and is the mainstay of therapy (see illustration); (see illustration). Systemic antibiotics are usually given, although they offer little beyond adequate incision and drainage. Sodium dicloxacillin or cephalexin, 1 g daily in divided doses by mouth for 10 days, is usually effective. Doxycycline 100 mg twice daily, trimethoprim-sulfamethoxazole DS one tablet twice daily, and clindamycin 150–300 mg twice daily are effective in treating MRSA. Recurrent furunculosis may be effectively treated with a combination of cephalexin, 250–500 mg four times daily for 2–4 weeks, and rifampin, 300 mg twice daily for 5 days during this period. Chronic clindamycin, 150–300 mg daily for 1–2 months, may also cure recurrent furunculosis. Family members and intimate contacts may need evaluation for staphylococcal carrier state and perhaps concomitant treatment. Applications of topical 2% mupirocin to the nares, axillae, and anogenital areas twice daily for 5 days may eliminate the staphylococcal carrier state, although resistance is increasing.

Fig.

Appearance of abscess after incision, drainage, and packing. (Reproduced, with permission, from Chesnutt MS et al: *Office & Bedside Procedures*. Originally published by Appleton & Lange. Copyright © 1992 by The McGraw-Hill Companies, Inc.)

Local Measures

Immobilize the part and avoid overmanipulation of inflamed areas. Use moist heat to help larger lesions "localize." Use surgical incision and drainage *after* the lesions are "mature." To incise and drain an acute staphylococcal paronychia, insert a flat metal spatula or sharpened hardwood stick into the nail fold where it adjoins the nail. This will release pus from a mature lesion (see illustration); (see illustration).

Fig.

Incision of a paronychia. (Reproduced, with permission, from Chesnutt MS et al: *Office & Bedside Procedures*. Originally published by Appleton & Lange. Copyright © 1992 by The McGraw-Hill Companies, Inc.)

Prognosis

Recurrent crops may harass the patient for months or years.

Epidermal Inclusion Cysts

Essentials of Diagnosis

- Firm dermal papule or nodule.
- Overlying black comedone or "punctum."
- Expressible foul-smelling cheesy material.
- May become red and drain, mimicking an abscess.

General Considerations

Epidermal inclusion cysts (EICs) are common, benign growths of the upper portion of the hair follicle. They are common in Gardner syndrome and may be the first stigmata of the condition.

Epidermal inclusion cysts favor the face and trunk and may complicate nodulocystic acne vulgaris. Individual lesions range in size from 0.3 cm to several centimeters. An overlying pore or punctum is characteristic. Lateral pressure may lead to extrusion of a foul-smelling, cheesy material.

Differential Diagnosis

EICs are distinguished from lipomas by being more superficial (in the dermis not the subcutaneous fat) and by their overlying punctum. Many other benign and malignant tumors may superficially resemble EICs, but all lack the punctum.

Complications

EICs may rupture, creating an acute inflammatory nodule very similar to an abscess. Cultures of the expressed material will be sterile.

Treatment

Treatment is not required if asymptomatic. Inflamed lesions may be treated with incision and drainage or intralesional triamcinolone acetomide 5–10 mg/mL. For large or symptomatic cysts, surgical excision is curative.

Lee HE et al. Comparison of the surgical outcomes of punch incision and elliptical excision in treating epidermal inclusion cysts: a prospective, randomized study. Dermatol Surg. 2006 Apr;32(4):520–5.

Sukal SA et al. Safer and less unpleasant incision and drainage of epidermal inclusion cysts. Dermatol Surg. 2006 Sep; 32(9):1214–5.

Photodermatitis

Essentials of Diagnosis

- Painful or pruritic erythema, edema, or vesiculation on sun-exposed surfaces: the face, neck, hands, and "V" of the chest.
- Inner upper eyelids spared, as is the area under the chin.

General Considerations

In most cases, photosensitivity is an acute or chronic skin reaction due to hypersensitivity to ultraviolet radiation. It is caused by certain drugs, by lupus erythematosus, and some inherited disorders including the porphyrias. Contact photosensitivity may occur with plants, perfumes, and sunscreens.

Photodermatitis is manifested as phototoxicity—a tendency for the individual to sunburn more easily than expected—or, as photoallergy, a true immunologic reaction that often presents with dermatitis.

Clinical Findings

Symptoms and Signs

The acute inflammatory skin reaction, if severe enough, is accompanied by pain, fever, gastrointestinal symptoms, malaise, and even prostration, but this is very rare. Signs include erythema, edema, and possibly vesiculation and oozing on exposed surfaces. Peeling of the epidermis and pigmentary changes often result. The key to diagnosis is localization of the rash to photoexposed areas, though these eruptions may become generalized with time to involve even photoprotected areas (see photograph). The lower lip may be affected.

Fig.

Photodistribution. V of the chest and arms. (Reproduced, with permission, from Bondi EE, Jegasothy BV, Lazarus GS [editors]: *Dermatology: Diagnosis & Treatment*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Laboratory Findings

Blood and urine tests are generally not helpful unless porphyria cutanea tarda is suggested by the presence of blistering, scarring, milia (white cysts 1–2 mm in diameter) and skin fragility of the dorsal hands, and facial hypertrichosis. Eosinophilia may be present in chronic photoallergic responses.

Differential Diagnosis

The differential diagnosis is long. If a clear history of the use of a topical or systemic photosensitizer is not available and if the eruption is persistent, then a workup including biopsy and light testing may be required. Photodermatitis must be differentiated from contact dermatitis that may develop from one of the many substances in suntan lotions and oils, as these may often have a similar distribution. Sensitivity to actinic rays may also be part of a more serious condition such as porphyria cutanea tarda (see photograph) or lupus erythematosus. These disorders are diagnosed by appropriate blood or urine tests. Phenothiazines, quinine or quinidine, griseofulvin, sulfonylureas (especially hydrochlorothiazide), NSAIDs, and antibiotics (eg, some tetracyclines, quinolone, trimethoprim-sulfamethoxazole) may photosensitize the skin. PMLE is a very common idiopathic photodermatitis and often has its onset in the third to fourth decades except in Native Americans and Latinos, in whom it may present in childhood. PMLE is chronic in nature. Transitory periods of spontaneous remission do occur. The action spectrum of PMLE may also extend into the long ultraviolet wavelengths (UVA; 320–400 nm). Drug-induced photosensitivity is triggered by UVA.

Complications

Some individuals continue to be chronic light reactors even when they apparently are no longer exposed to photosensitizing drugs.

Prevention

While sunscreens are useful agents in general and should be used by persons with photosensitivity, patients may react to such low amounts of energy that sunscreens alone may not be sufficient. Sunscreens with an SPF of 30–60 and broad UVA coverage, containing dicamphor sulfonic acid (Mexoryl SX), avobenzone (Parasol 1789), titanium dioxide, and micronized zinc oxide, are especially useful in patients with photoallergic dermatitis. Photosensitivity due to porphyria is not prevented by sunscreens and requires barrier protection (clothing) to prevent outbreaks.

Treatment

Specific Measures

Drugs should be suspected in cases of photosensitivity even if the particular medication (such as hydrochlorothiazide) has been used for months.

Local Measures

When the eruption is vesicular or weepy, treatment is similar to that of any acute dermatitis, using cooling and soothing wet dressing.

Sunscreens should be used as described above. Mid-potency to high-potency topical corticosteroids are of limited benefit in sunburn reactions but may help in PMLE and photoallergic reactions. Since the face is often involved, close monitoring for corticosteroid side effects is recommended.

Systemic Measures

Aspirin may have some value for fever and pain of acute sunburn. Systemic corticosteroids in doses as described for acute contact dermatitis may be required for severe photosensitivity reactions. Otherwise, different photodermatoses are treated in specific ways.

Patients with severe photoallergy may require immunosuppressives, such as azathioprine, in the range of 50–150 mg/d, or cyclosporine, 3–5 mg/kg/d.

Prognosis

The most common phototoxic sunburn reactions are usually benign and self-limited. PMLE and some cases of photoallergy can persist for years.

Leg Ulcers Secondary to Venous Insufficiency

Essentials of Diagnosis

- Past history of varicosities, thrombophlebitis, or postphlebitic syndrome.
- Irregular ulceration, often on the medial aspect of the lower legs above the malleolus.
- Edema of the legs, varicosities, hyperpigmentation, and red and scaly areas (stasis dermatitis) and scars from old ulcers support the diagnosis.

General Considerations

Patients at risk may have a history of venous insufficiency, either with obvious varicosities or with a past history of thrombophlebitis, or with immobility of the calf muscle group (paraplegics, etc). Red, pruritic patches of stasis dermatitis often precede ulceration. Because venous insufficiency plays a role in between 75% and 90% of lower leg ulcerations, testing of venous competence is a required part of a leg ulcer evaluation even when no changes of venous insufficiency are present.

Clinical Findings

Symptoms and Signs

Classically, chronic edema is followed by a dermatitis, which is often pruritic. These changes are followed by hyperpigmentation, skin breakdown, and eventually sclerosis of the skin of the lower leg (Plate 45); (see photograph). The ulcer base may be clean, but it often has a yellow fibrin eschar that may require surgical removal (see photograph); (see photograph). Ulcers that appear on the feet, toes, or above the knees should be approached with other diagnoses in mind.

Venous stasis ulcer. (Reproduced, with permission, from Bondi EE, Jegasothy BV, Lazarus GS [editors]: *Dermatology: Diagnosis & Treatment*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Laboratory Findings

Thorough evaluation of the patient's vascular system (including measurement of the ankle/brachial index [ABI]) is essential. If the ABI is less than 0.7, the patient should be referred to a vascular surgeon for surgical evaluation. Doppler and light rheography examinations as office procedures are usually sufficient (except in the diabetic) to elucidate the cause of most vascular cases of lower leg ulceration.

Differential Diagnosis

The differential includes vasculitis (see photograph), pyoderma gangrenosum, arterial ulcerations, infection, trauma, skin cancer, arachnid bites, and sickle cell anemia. When the diagnosis is in doubt, a punch biopsy from the border (not base) of the lesion may be helpful.

Fig.

The hallmark of hypersensitivity vasculitis is palpable purpura. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Prevention

Compression stockings to reduce edema are the most important means of prevention. Compression should achieve a pressure of 30 mm Hg below the knee and 40 mm Hg at the ankle. The stockings should not be used in patients with arterial insufficiency with an ABI less than 0.7. Pneumatic sequential compression devices may be of great benefit when edema is refractory to standard compression dressings.

Treatment

Local Measures

Clean the base of the ulcer with saline or cleansers such as Saf-Clens. A curette or small scissors can be used to remove the yellow fibrin eschar; local anesthesia may be used if the areas are very tender.

The ulcer is treated with metronidazole gel to reduce bacterial growth and odor. Any red dermatitic skin is treated with a medium- to high-potency corticosteroid ointment. The ulcer is then covered with an occlusive hydroactive dressing (DuoDerm, Hydrasorb or Cutinova) or a polyurethane foam (Allevyn) followed by an Unna zinc paste boot. This is changed weekly. The ulcer should begin to heal within weeks, and healing should be complete within 4–6 months. If the patient is diabetic, becaplermin (Regranex) may be applied to those ulcers that are not becoming smaller or developing a granulating base. Some ulcerations require grafting. Full- or split-thickness grafts often do not take, and pinch grafts (small shaves of skin laid onto the bed) may be effective. Cultured epidermal cell grafts may accelerate wound healing, but they are very expensive. They should be considered in refractory ulcers, especially those that have not healed after a year or more of conservative therapy.

No topical intervention has evidence to suggest that it will improve healing of arterial leg ulcers.

Systemic Therapy

Pentoxifylline, 400 mg three times daily administered with compression dressings, is beneficial in accelerating healing of venous insufficiency leg ulcers. Zinc supplementation is occasionally beneficial in patients with low serum zinc levels. If cellulitis accompanies the ulcer, systemic antibiotics are recommended: dicloxacillin, 250 mg orally four times a day, or levofloxacin, 500 mg once daily for 1–2 weeks is usually adequate. Routine use of antibiotics and treating bacteria isolated from a chronic ulcer without clinical evidence of infection is discouraged. If the ulcer fails to heal or there is a persistent draining tract in the ulcer, an underlying osteomyelitis should be sought.

Prognosis

The combination of compression stockings and newer dressings enables venous stasis ulcers to heal within months. Topical growth factors, antibiotics, debriding agents, and xenografts and autografts can be considered in recalcitrant cases. If the ABI is less than 0.5, the prognosis for healing is poor. Ongoing control of edema is essential to prevent recurrent ulceration.

Pigmentary Disorders

*Hirsutism is discussed in Chapter 26: Endocrine Disorders.

Although the color of skin may be altered by many diseases and agents, the vast majority of patients have either an increase or decrease in pigment secondary to some inflammatory disease such as acne or atopic dermatitis.

Other pigmentary disorders include those resulting from exposure to exogenous pigments such as carotenemia, argyria, and tattooing. Other endogenous pigmentary disorders are attributable to metabolic substances—including hemosiderin (iron)—in purpuric processes; or to homogentisic acid in ochronosis; and bile pigments.

Classification

First, determine whether the disorder is hyperpigmentation or hypopigmentation, ie, an increase or decrease in normal skin colors. Each may be considered to be primary or to be secondary to other disorders.

Primary Pigmentary Disorders

Hyperpigmentation

The disorders in this category are nevoid and congenital or acquired, and include pigmented nevi, ephelides (juvenile freckles), and lentigines (senile freckles) (see photograph). Hyperpigmentation occurs also in arsenical melanosis or in association with Addison disease. **Melasma (chloasma)** occurs as patterned hyperpigmentation of the face, usually as a direct effect of estrogens. It occurs not only during pregnancy but also in 30–50% of women taking oral contraceptives, and rarely in men. One report suggests that such men have low testosterone and elevated luteinizing hormone levels.

Fig.

Close-up of lentigines. The patient has multiple lentigines syndrome. Note that lentigines are darkly colored (dark brown) and macular. They have normal or slightly thickened skin markings. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton

& Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Hypopigmentation and depigmentation

The disorders in this category are vitiligo, albinism, and piebaldism. In vitiligo, pigment cells (melanocytes) are destroyed (Plate 46); (see photograph); (see photograph). Vitiligo, present in approximately 1% of the population, may be associated with other autoimmune disorders such as autoimmune thyroid disease, pernicious anemia, diabetes mellitus, and Addison disease.

Plate 46.

Vitiligo of the hands. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

Fig.

The chest of a patient with widespread vitiligo. The white areas are totally depigmented. The depigmentation is caused by destruction of pigment cells within the epidermis. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Secondary Pigmentary Disorders

Any damage to the skin (irritation, allergy, infection, excoriation, burns, or dermatologic therapy such as chemical peels and freezing with liquid nitrogen) may result in hyperpigmentation or hypopigmentation. Several disorders of clinical importance are described below.

Hyperpigmentation

The most common type of secondary hyperpigmentation occurs after another dermatologic condition, such as acne, and is most commonly seen in moderately complexioned persons (Asians, Hispanics, and light-skinned African Americans). It is called postinflammatory hyperpigmentation.

Pigmentation may be produced by certain drugs, eg, chloroquine, chlorpromazine, minocycline, and amiodarone. Fixed drug eruptions to phenolphthalein in laxatives, to trimethoprim-sulfamethoxazole, to NSAIDs, and to tetracyclines, for example, are further causes.

Hypopigmentation

Leukoderma is a disorder that may complicate atopic dermatitis, lichen planus, psoriasis, DLE, and lichen simplex chronicus. Practitioners must exercise special care in using liquid nitrogen on any patient with olive or darker complexions, since doing so may result in hypopigmentation or depigmentation, at times permanent. Intralesional or intra-articular injections of high concentrations of corticosteroids may also cause localized temporary hypopigmentation.

Differential Diagnosis

The evaluation of pigmentary disorders is helped by Wood's light, which accentuates epidermal pigmentation and highlights hypopigmentation. Depigmentation, as seen in vitiligo, enhances with Wood's light examination, whereas postinflammatory hypopigmentation does not.

Complications

Actinic keratoses and skin cancers are more likely to develop in persons with vitiligo. Severe emotional trauma may occur in extensive vitiligo and other types of hypopigmentation and hyperpigmentation, particularly in naturally dark-skinned persons.

Treatment & Prognosis

Hyperpigmentation

Therapeutic bleaching preparations generally contain hydroquinone. Hydroquinone has occasionally caused unexpected hypopigmentation, hyperpigmentation, or even secondary ochronosis and pigmented milia, particularly with prolonged use.

The role of exposure to ultraviolet light cannot be overstressed as a factor promoting or contributing to most disorders of hyperpigmentation, and such exposure should be minimized. Melasma, ephelides, and postinflammatory hyperpigmentation may be treated with varying success with 3–4% hydroquinone cream, gel, or solution and a sunscreen containing UVA photoprotectants (Avobenzone, Mexoryl, zinc oxide, titanium dioxide). Tretinoin cream, 0.025–0.05%, may be added. Superficial melasma responds well, but if there is predominantly dermal deposition of pigment (does *not* enhance with Wood's light), the prognosis is poor. Response to therapy takes months and requires avoidance of sunlight. Hyperpigmentation often recurs after treatment if the skin is exposed to ultraviolet light. Solar lentigines respond to liquid nitrogen application. Tretinoin, 0.1% cream and tazarotene 0.1% used over 10 months, will fade solar lentigines (liver spots), hyperpigmented facial macules in Asians, and postinflammatory hyperpigmentation in blacks. New laser systems for the removal of epidermal and dermal pigments are available, and referral should be considered for patients whose responses to medical treatment are inadequate.

Hypopigmentation

In secondary hypopigmentation, repigmentation may occur spontaneously. Cosmetics such as Covermark and Dermablend are highly effective for concealing disfiguring patches. Therapy of vitiligo is long and tedious, and the patient must be strongly motivated. If less than 20% of the skin is involved (most cases), topical tacrolimus 0.1% twice daily is the first-line therapy. A superpotent corticosteroid may also be used, but local skin atrophy from prolonged use may ensue. With 20–25% involvement, narrowband UVB or oral PUVA is best. Severe phototoxic response (sunburn) may occur with PUVA. The face and upper chest respond best, and the fingertips and the genital areas do not respond as well to treatment. Years of treatment may be required. Newer techniques of using epidermal autografts and cultured epidermis combined with PUVA therapy give hope for surgical correction of vitiligo.

Baldness (Alopecia)

Baldness Due to Scarring (Cicatricial Alopecia)

Cicatricial baldness may occur following chemical or physical trauma, lichen planopilaris, bacterial or fungal infections, severe herpes zoster, chronic DLE, scleroderma, and excessive ionizing radiation. The specific cause is often suggested by the history, the distribution of hair loss, and the appearance of the skin, as in lupus erythematosus. Biopsy is useful in the diagnosis of scarring alopecia, but specimens must be taken from the active border and not from the scarred central zone.

Scarring alopecias are irreversible and permanent. It is important to diagnose and treat the scarring process as early in its course as possible.

Baldness Not Associated with Scarring

Nonscarring alopecia may occur in association with various systemic diseases such as SLE, secondary syphilis, hyperthyroidism or hypothyroidism, iron deficiency anemia, and pituitary insufficiency. The only treatment necessary is prompt and adequate control of the underlying disorder and usually leads to regrowth of the hair.

Androgenetic (pattern) baldness, the most common form of alopecia, is of genetic predetermination. The earliest changes occur at the anterior portions of the calvarium on either side of the "widow's peak" and on the crown (vertex). The extent of hair loss is variable and unpredictable. Minoxidil 5% is available over the counter and can be specifically recommended for persons with recent onset (< 5 years) and smaller areas of alopecia. Approximately 40% of patients treated twice daily for a year will have moderate to dense growth. Finasteride (Propecia), 1 mg orally daily, has similar efficacy and may be additive to minoxidil. As opposed to minoxidil, finasteride is used only in males.

Hair loss or thinning of the hair in women results from the same cause as common baldness in men (androgenetic alopecia) and may be treated with topical minoxidil. A workup consisting of determination of serum testosterone, DHEAS, iron, total iron binding capacity, thyroid function tests, and a complete blood count will identify most other causes of hair thinning in premenopausal women. Women who complain of thin hair but show little evidence of alopecia need follow-up, because more than 50% of the scalp hair can be lost before the clinician can perceive it.

Telogen effluvium is transitory increase in the number of hairs in the telogen (resting) phase of the hair growth cycle. This may occur spontaneously, may appear at the termination of pregnancy, may be precipitated by "crash dieting," high fever, stress from surgery or shock, malnutrition, or may be provoked by hormonal contraceptives. Whatever the cause, telogen effluvium usually has a latent period of 2–4 months. The prognosis is generally good. The condition is diagnosed by the presence of large numbers of hairs with white bulbs coming out upon gentle tugging of the hair. Counts of hairs lost by the patient on combing or shampooing often exceed 150 per day, compared to an average of 70–100. In one study, a major cause of telogen effluvium was found to be iron deficiency, and the hair counts bore a clear relationship to serum iron levels.

Alopecia areata is of unknown cause but is believed to be an immunologic process. Typically, there are patches that are perfectly smooth and without scarring (see photograph); (see photograph). Tiny hairs 2–3 mm in length, called "exclamation hairs," may be seen. Telogen hairs are easily dislodged from the periphery of active lesions. The beard, brows, and lashes may be involved. Involvement may extend to all of the scalp hair (alopecia totalis) or to all scalp and body hair (alopecia universalis). Severe forms may be treated by systemic corticosteroid therapy, although recurrences follow discontinuation of therapy. Alopecia areata is occasionally associated with Hashimoto thyroiditis, pernicious anemia, Addison disease, and vitiligo.

Fig.

Alopecia areata (nonscarring). (Reproduced, with permission, from Bondi EE, Jegasothy BV, Lazarus GS [editors]: *Dermatology: Diagnosis & Treatment*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Fig.

Alopecia areata. A bald patch is seen, and gray or white hairs are typical. (Courtesy of S Goldstein.)

Intralesional corticosteroids are frequently effective for alopecia areata. Triamcinolone acetonide in a concentration of 2.5–10 mg/mL is injected in aliquots of 0.1 mL at approximately 1- to 2-cm intervals, not exceeding a total dose of 30 mg per month for adults. Alternatively, anthralin 0.5% ointment, used daily, may help some patients. Alopecia areata is usually self-limiting, with complete regrowth of hair in 80% of patients with focal disease. Some mild cases are resistant to treatment, as are the extensive totalis and universalis types. Both topical diphencyprone and squaric acid dibutylester, have been used to treat persistent alopecia areata. The principle is to sensitize the skin, then intermittently apply weaker concentrations to produce and maintain a slight dermatitis. Hair regrowth in 3–6 months in some patients has been reported to be remarkable. Long-term safety and efficacy have not been established. Support groups for patients with extensive alopecia areata are very beneficial.

In **trichotillomania** (the pulling out of one's own hair), the patches of hair loss are irregular and short growing hairs are always present, since they cannot be pulled out until they are long enough. The patches are often unilateral, occurring on the same side as the patient's dominant hand. The patient may be unaware of the habit.

Nail Disorders

Morphologic Abnormalities of the Nails

Classification

Acquired nail disorders may be classified as local or those associated with systemic or generalized skin diseases.

Local Nail Disorders

Onycholysis (distal separation of the nail plate from the nail bed, usually of the fingers) is caused by excessive exposure to water, soaps, detergents, alkalies, and industrial cleaning agents. Candidal infection of the nail folds and subungual area, nail hardeners, and drug-induced photosensitivity may cause onycholysis, as may hyperthyroidism, hypothyroidism, and psoriasis (see photograph).

Fig.

Onycholysis and salmon patch associated with psoriasis. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

1. Distortion of the nail occurs as a result of chronic inflammation of the nail matrix underlying the eponychial fold. Such changes may also be caused by warts, tumors, or cysts, impinging on the nail matrix.

2. Discoloration and crumbly thickened nails are noted in dermatophyte infection and psoriasis.

3. Allergic reactions (to resins in undercoats and polishes or to nail glues) are characterized by onycholysis or by grossly distorted, hypertrophic, and misshapen nails.

Nail Changes Associated With Systemic or Generalized Skin Diseases

Beau lines (transverse furrows) may follow any serious systemic illness (see photograph).

Fig.

Beau's lines. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Orginally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

1. Atrophy of the nails may be related to trauma or to vascular or neurologic disease.

2. Clubbed fingers may be due to the prolonged hypoxemia associated with cardiopulmonary disorders (Plate 47). (See Chapter 9: Pulmonary Disorders.)

Plate 47.

Clubbing of the fingers in congenital heart disease. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

3. Spoon nails may be seen in anemic patients.

4. Stippling or pitting of the nails is seen in psoriasis, alopecia areata, and hand eczema (see photograph); (see photograph).

5. Nail hyperpigmentation may be caused by many chemotherapeutic agents, but especially the taxanes.

Differential Diagnosis

Onychomycosis may cause nail changes identical to those seen in psoriasis. Careful examination for more characteristic lesions elsewhere on the body is essential to the diagnosis of the nail disorders. Cancer should be suspected (eg, Bowen disease or squamous cell carcinoma) as the cause of any persistent solitary subungual or periungual lesion.

Complications

Toenail changes may lead to an ingrown nail—in turn often complicated by bacterial infection and occasionally by exuberant granulation tissue. Poor manicuring and poorly fitting shoes may contribute to this complication. Cellulitis may result.

Treatment & Prognosis

Treatment consists usually of careful debridement and manicuring and, above all, reduction of exposure to irritants (soaps, detergents, alkali, bleaches, solvents, etc). Longitudinal grooving due to temporary lesions of the matrix, such as warts, synovial cysts, and other impingements, may be cured by removal of the offending lesion.

Tinea Unguium (Onychomycosis)

Tinea unguium is a trichophyton infection of one or more (but rarely all) fingernails or toenails. The species most commonly found is *T rubrum.*"Saprophytic" fungi may rarely (< 5%) cause onychomycosis.

The nails are lusterless, brittle, and hypertrophic, and the substance of the nail is friable (see photograph). Laboratory diagnosis is mandatory since only 50% of dystrophic nails are due to dermatophytosis. Portions of the nail should be cleared with 10% KOH and examined under the microscope for hyphae. Fungi may also be cultured. Periodic acid-Schiff stain of a histologic section of the nail plate will also demonstrate the fungus readily. Each technique is positive in only 50% of cases so several different tests may need to be performed.

Onychomycosis is difficult to treat because of the long duration of therapy required and the frequency of recurrences. Fingernails respond more readily than toenails. For toenails, treatment is limited to patients with discomfort, inability to exercise, and immune compromise.

In general, systemic therapy is required to effectively treat nail onychomycosis. Topical therapy has limited value and the adjunctive value of surgical procedures is unproven. Fingernails can virtually always be cured and toenails are cured 35–50% of the time and are clinically improved about 75% of the time. In all cases, before treatment, the diagnosis should be confirmed. The costs of the various treatment options should be known and the most cost-effective treatment chosen. Drug interactions must be avoided. Ketoconazole, due to its higher risk for hepatotoxicity, is not recommended to treat any form of onychomycosis. For fingernails, ultramicronized griseofulvin 250 mg orally three times daily for 6 months can be effective. Alternative treatments are (in order of preference) oral terbinafine 250 mg/d for 6 weeks, oral itraconazole 400 mg/d for 7 days each month for 2 months, and oral itraconazole 200 mg/d for 2 months. Off-label use of fluconazole, 400 mg once weekly for 6 months, can also be effective, but there is limited evidence for this option. Once clear, fingernails usually remain free of disease for some years.

Onychomycosis of the toenails does not respond to griseofulvin therapy or topical treatments. The best treatment, which is also FDA approved, is oral terbinafine 250 mg daily for 12 weeks. Liver function tests and a complete blood count with platelets are performed monthly during treatment. Pulse oral itraconazole 200 mg twice daily for 1 week per month for 3 months is inferior to standard terbinafine treatments, but it is an acceptable alternative for those unable to take terbinafine. The courses of terbinafine or itraconazole may need to be repeated 6 months after the first treatment cycle if fungal cultures of the nail are still positive.

Dermatitis Medicamentosa (Drug Eruption)

Essentials of Diagnosis

- Usually, abrupt onset of widespread, symmetric erythematous eruption.
- May mimic any inflammatory skin condition.
- Constitutional symptoms (malaise, arthralgia, headache, and fever) may be present.

General Considerations

As is well recognized, only a minority of cutaneous drug reactions result from allergy. True allergic drug reactions involve prior exposure, an "incubation" period, reactions to doses far below the therapeutic range, manifestations different from the usual pharmacologic effects of the drug, involvement of only a small portion of the population at risk, restriction to a limited number of syndromes (anaphylactic and anaphylactoid, urticarial, vasculitic, etc), and reproducibility.

Rashes are among the most common adverse reactions to drugs and occur in 2–3% of hospitalized patients. Amoxicillin, trimethoprim-sulfamethoxazole, and ampicillin or penicillin are the most common causes of urticarial and maculopapular reactions. Toxic epidermal necrolysis and Stevens-Johnson syndrome are most commonly produced by sulfonamides and anticonvulsants. Phenolphthalein, pyrazolone derivatives, tetracyclines, NSAIDs, trimethoprim-sulfamethoxazole, and barbiturates are the major causes of fixed drug eruptions.

Clinical Findings

Symptoms and Signs

Drug eruptions are generally classified as "simple" or "complex." Simple drug eruptions involve an exanthem, usually appear in the second week of drug therapy, and have no associated constitutional or laboratory findings. Antibiotics, including the penicillins and quinolones are the most common causes. Complex drug eruptions occur during the third week of treatment on average and have constitutional and laboratory findings. These may include fevers, chills, hematologic abnormalities (especially eosinophilia), and abnormal liver or kidney function. A mnemonic for complex eruptions is "DRESS" (**DR**ug Eruption with **E**osinophilia and **S**ystemic **S**ymptoms). The most common causes are the long-acting sulfonamides, allopurinol, and anticonvulsants. The use of anticonvulsants to treat bipolar disorder and chronic pain has led to an apparent increase in these reactions. Coexistent reactivation of Epstein-Barr virus, HHV-6, or cytomegalovirus is often present and may be important in the pathogenesis of these complex drug eruptions. Table 6–3 summarizes the types of skin reactions, their appearance and distribution, and the common offenders in each case.

Table 6–3. Skin reactions due to systemic drugs.			
Reaction	**Appearance**	**Distribution and Comments**	**Common Offenders**
Toxic erythema	Morbilliform, maculopapular, exanthematous reactions.	The most common skin reaction to drugs. Often more pronounced on the trunk than on the extremities. In previously exposed patients, the rash may start in 2–3 days. In the first course of treatment, the eruption often appears about the seventh to ninth days.	Antibiotics (especially ampicillin and trimethoprim-sulfamethoxazole), sulfonamides and related compounds (including thiazide diuretics, furosemide, and sulfonylurea hypoglycemic agents), and barbiturates.

		Fever may be present.	
Erythema multiforme major	Target-like lesions. Bullae may occur. Mucosal involvement.	Usually trunk and proximal extremities.	Sulfonamides, anticonvulsants, and NSAIDs.
Erythema nodosum	Inflammatory cutaneous nodules.	Usually limited to the extensor aspects of the legs. May be accompanied by fever, arthralgias, and pain.	Oral contraceptives.
Allergic vasculitis	Inflammatory changes may present as urticaria that lasts over 24 hours, hemorrhagi	Most severe on the legs.	Sulfonamides, phenytoin, propylthiouracil.

	c papules ("palpable purpura"), vesicles, bullae, or necrotic ulcers.		
Exfoliative dermatitis and erythroderma	Red and scaly.	Entire skin surface.	Allopurinol, sulfonamides, isoniazid, anticonvulsants. gold, or carbamazepine.
Photosensitivity: increased sensitivity to light, often of ultraviolet A wavelengths, but may be due to UVB or visible light as well	Sunburn, vesicles, papules in photodistributed pattern.	Exposed skin of the face, the neck, and the backs of the hands and, in women, the lower legs. Exaggerated response to ultraviolet light.	Sulfonamides and sulfonamide-related compounds (thiazide diuretics, furosemide, sulfonylureas), tetracyclines, phenothiazines, sulindac, amiodarone,

			voriconazole, and NSAIDs.
Drug-related lupus erythematosus	May present with a photosensitive rash, annular lesions or psoriasis on upper trunk.	Less severe than systemic lupus erythematosus, sparing the kidneys and central nervous system. Recovery often follows drug withdrawal.	Diltiazem, etanercept, hydrochlorothiazide, infliximab, lisinopril
Lichenoid and lichen planus–like eruptions (see photograph)	Pruritic, erythematous to violaceous polygonal papules that coalesce or expand to form plaques.	May be in photo- or nonphotodistributed pattern.	Carbamazepine, furosemide, gold salts, hydroxychloroquine, methyldopa, phenothiazines, propranolol, quinidine, quinine, sulfonylureas, tetracyclines,

			thiazides, and triprolidine.
Fixed drug eruptions (see photograph)	Single or multiple demarcated, round, erythematous plaques that often become hyperpigmented.	Recur at the same site when the drug is repeated. Hyperpigmentation, if present, remains after healing.	Numerous drugs, including antimicrobials, analgesics, barbiturates, cardiovascular drugs, heavy metals, antiparasitic agents, antihistamines, phenolphthalein, ibuprofen, and naproxen.
Toxic epidermal necrolysis (see photograph)	Large sheets of erythema, followed by separation, which looks like scalded skin.	Rare.	In adults, the eruption has occurred after administration of many classes of drugs, particularly anticonvulsants (lamotrigine

			and others), antibiotics, sulfonamides, and NSAIDs.
Urticaria	Red, itchy wheals that vary in size from < 1 cm to many centimeters. May be accompanied by angioedema.	Chronic urticaria is rarely caused by drugs.	Acute urticaria: penicillins, NSAIDs, sulfonamides, opiates, and salicylates. Angioedema is common in patients receiving ACE inhibitors.
Pigmentary changes	Flat hyperpigmented areas.	Forehead and cheeks (chloasma, melasma). The most common pigmentary disorder associated with drug ingestion. Improvement	Oral contraceptives are the usual cause.

		is slow despite stopping the drug.	
	Blue-gray discoloration.	Light-exposed areas.	Chlorpromazine and related phenothiazines.
	Brown or blue-gray pigmentation.	Generalized.	Heavy metals (silver, gold, bismuth, and arsenic).
	Yellow color.	Generalized.	Usually quinacrine.
	Blue-black patches on the shins (see photograph).		Minocycline, chloroquine.
	Blue-black pigmentation of the nails and palate and depigmentation of the		Chloroquine.

	hair.		
	Slate-gray color (see photograph).	Primarily in photoexposed areas.	Amiodarone.
	Brown discoloration of the nails.	Especially in more darkly pigmented patients.	Hydroxyurea.
Psoriasiform eruptions	Scaly red plaques.	May be located on trunk and extremities. Palms and soles may be hyperkeratotic. May cause psoriasiform eruption or worsen psoriasis.	Antimalarials, lithium, -blockers, and tumor necrosis factor (TNF)-inhibitors.
Pityriasis rosea–like eruptions	Oval, red, slightly raised patches with central scale.	Mainly on the trunk.	Barbiturates, bismuth, captopril, clonidine, gold salts, methopromazi

			ne, metoprolol, metronidazole, and tripelennamine.

ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs.

Laboratory Findings

Routinely ordered blood work is of no value in the diagnosis of simple drug eruptions. In complex drug eruptions, the CBC, liver biochemical tests, and renal function tests should be monitored. Skin biopsies may be helpful in making the diagnosis.

Differential Diagnosis

Observation after discontinuation, which may be a slow process, helps establish the diagnosis. Rechallenge, though of theoretical value, may pose a danger to the patient and is best avoided.

Complications

Some cutaneous drug reactions may be associated with visceral involvement. The organ systems involved depend on the individual medication or drug class. Most common is an infectious mononucleosis-like illness and hepatitis associated with administration of anticonvulsants.

Treatment

General Measures

Systemic manifestations are treated as they arise (eg, anemia, icterus, purpura). Antihistamines may be of value in urticarial and angioneurotic reactions. Epinephrine 1:1000, 0.5–1 mL intravenously or subcutaneously, should be used as an emergency measure. In complex eruptions, systemic corticosteroids may be required, starting at about 1 mg/kg/d and tapering very slowly.

Local Measures

Extensive blistering eruptions resulting in erosions and superficial ulcerations demand hospitalization and nursing care as for burn patients.

Prognosis

Drug rash usually disappears upon withdrawal of the drug and proper treatment.

Redness

Redness may be due to hyperemia of the conjunctival, episcleral, or ciliary vessels (eFigure 7–1: photograph); erythema of the eyelids; or subconjunctival hemorrhage (eFigure 7–2: photograph). The major differential diagnoses are conjunctivitis, corneal disorders, acute glaucoma, and acute uveitis (see Table 7–1).

eFigure 7–1.

Hyperemia of conjunctival and episcleral or ciliary vessels.

eFigure 7–2.

Subconjunctival hemorrage. (Courtesy of Ed Lee.)

Table 7–1. The inflamed eye: Differential diagnosis of common causes.

	Acute Conjunctivitis	**Acute Anterior Uveitis (Iritis)**	**Acute Angle-Closure Glaucoma**	**Corneal Trauma or Infection**
Incidence	Extremely common	Common	Uncommon	Common
Discharge	Moderate to copious	None	None	Watery or purulent
Vision	No effect on vision	Often blurred	Markedly blurred	Usually blurred
Pain	Mild	Moderate	Severe	Moderate to severe
Conjunctival injection	Diffuse; more toward fornices	Mainly circumcorneal	Mainly circumcorneal	Mainly circumcorneal
Cornea	Clear	Usually clear	Steamy	Clarity change related to cause
Pupil size	Normal	Small	Moderately dilated and fixed	Normal or small
Pupillary light response	Normal	Poor	None	Normal

Intraocular pressure	Normal	Usually normal but may be low or elevated	Markedly elevated	Normal
Smear	Causative organisms	No organisms	No organisms	Organisms found only in corneal infection

Wirbelauer C. Management of the red eye for the primary care physician. Am J Med. 2006 Apr;119(4):302–6. [PMID: 16564769]

Ocular Discomfort

Ocular pain may be caused by trauma, infection, inflammation, or sudden increase in intraocular pressure.

Foreign body sensation may be due to corneal or conjunctival foreign bodies, disturbance of the corneal epithelium, or rubbing of eyelashes against the cornea (trichiasis).

Photophobia is usually due to corneal inflammation (keratitis) or anterior uveitis (iritis). Other causes are albinism, aniridia, cone dystrophy, or fever associated with various systemic infections.

Itching is characteristically associated with allergic eye disease.

Scratching and burning due to dryness of the eyes may be due to lacrimal gland hypofunction, including hypofunction caused by systemic disorders (eg, Sjögren disease) or drugs (eg, atropine-like agents); ocular surface disease; or dry environment.

Watering is usually due to inadequate tear drainage through obstruction of the lacrimal drainage system or malposition of the lower lid. Reflex tearing occurs with any disturbance of the corneal epithelium.

"Eyestrain" & Headache

Refractive error including presbyopia, inadequate illumination, and latent ocular deviation are possible causes of eyestrain. Headache is rarely due to ocular disorders but is a major symptom of giant cell arteritis, an important cause of visual loss in older individuals.
Conjunctival Discharge

Purulent discharge usually indicates bacterial infection of the conjunctiva, cornea, or lacrimal sac. Viral conjunctivitis or keratitis produces watery discharge; allergic conjunctivitis results in tearing, ropy discharge, and itching.
Visual Loss

Causes of blurred vision (reduced visual acuity) include refractive error, corneal opacities, cataract, intraocular inflammation (uveitis), vitreous hemorrhage, retinal detachment involving the macula, diabetic retinopathy, central retinal vein occlusion, central retinal artery occlusion, macular degeneration, and optic nerve disorders.

Monocular field loss usually indicates disease of the retina or optic nerve (see illustration). Important causes are chronic glaucoma, retinal detachment, branch retinal artery or vein occlusion, optic neuritis, and anterior ischemic optic neuropathy, all of which, especially chronic glaucoma, may be bilateral. Lesions of the optic chiasm, usually due to pituitary tumors, typically result in bitemporal field loss. Retrochiasmal lesions, usually due to cerebrovascular disease or tumor, cause contralateral homonymous field defects.

Fig.

Visual field defects due to various lesions of the optic pathways. (Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology*, 17th ed. McGraw-Hill, 2008.)

When to Refer

Patients with visual loss not due to refractive error should be referred to an ophthalmologist *emergently* if the vision loss is associated with pain or marked redness; is due to central retinal artery occlusion, retinal detachment with good central vision, or giant cell arteritis; or is of sudden onset in a diabetic. Patients should be referred *urgently* if the vision loss is associated with redness; is due to vitreous hemorrhage, retinal detachment, retinal vein occlusion, branch retinal artery occlusion, diabetic maculopathy, ischemic optic neuropathy, or optic neuritis; is of sudden onset due to macular degeneration; or occurs in association with dysthyroid eye disease.

Vortmann M et al. Acute monocular visual loss. Emerg Med Clin North Am. 2008 Feb;26(1):73–96. [PMID: 18249258]

Visual Impairment & Blindness

The World Health Organization (WHO) defines low vision as best corrected distant visual acuity in the better eye less than 20/60 but 20/400 or better, or widest diameter of the visual field subtending an angle of less than 20 degrees but greater than 10 degrees, and blindness as best corrected distant visual acuity in the better eye of less than 20/400 or less or widest diameter of the visual field subtending an angle of less than 10 degrees. Using this definition, it is estimated that 93-145 million people worldwide have low vision and 5-8 million are blind due to uncorrected refractive error, making it the most common cause of visual impairment. An estimated 124 million people worldwide have low vision and about 37 million worldwide are blind due to other causes. The most common causes of blindness are cataract, glaucoma, age-related macular degeneration, and diabetic retinopathy (all of which are increasing in prevalence, especially in older individuals) as well as trachoma. Overall, 75% of blindness worldwide is thought to be treatable or preventable.

In the United States, approximately 10 million people are blind or visually impaired, which also includes many with uncorrected refractive error. Legal blindness is defined as best corrected distant visual acuity of 20/200 or less in the better eye or widest diameter of visual field subtending less than 20 degrees. Most North American states require best corrected visual acuity with both eyes of 20/40 for an unrestricted driving license.

Diplopia

Double vision typically results from acquired ocular misalignment. This may be caused by central disorders of eye movements or cranial nerve palsies due to head injury, vascular, neoplastic, or inflammatory intracranial disease, or Wernicke syndrome; myasthenia gravis; or orbital disease including dysthyroid eye disease and muscle entrapment as a result of orbital blowout fracture. Monocular diplopia, which persists when the fellow eye is covered, is usually due to refractive error or lens opacities.

When to Refer

All patients with recent onset double vision should be referred urgently to an ophthalmologist or neurologist, particularly if there is multiple cranial nerve dysfunction or other neurologic abnormalities.

Any patient with recent onset isolated third nerve palsy, particularly if there is pupillary involvement or pain, must be referred emergently for neurologic assessment and possible investigation for intracranial aneurysm.

When to Admit

Patients with double vision due to giant cell arteritis may require emergency admission for high-dose corticosteroid therapy and close monitoring to ensure that treatment is adequate.

"Spots Before the Eyes" & "Flashing Lights"

Spots before the eyes (floaters) are often caused by benign vitreous opacities. However, they may also be caused by posterior vitreous detachment, vitreous hemorrhage, or posterior uveitis.

When to Refer

Patients with sudden onset of floaters, particularly when associated with flashing lights (photopsia), should be referred urgently to an ophthalmologist for dilated fundal examination to exclude a retinal tear or detachment.

Ocular Examination

Abbreviations and symbols commonly used in ophthalmology are listed in the accompanying box.

Abbreviations & Symbols Used in Ophthalmology.	
A or Acc	Accommodation
Ax or x	Axis of cylindric lens
BI or BO	Base-in or base-out (prism)
CF	Counting fingers
Cyl	Cylindric lens or cylinder
D	Diopter (lens strength)
E	Esophoria (latent convergent squint)
EOG	Electro-oculography
EOM	Extraocular muscles or movements

ERG	Electroretinography
ET	Esotropia (manifest convergent squint)
H	Hyperphoria (latent vertical squint)
HM	Hand movements
HT	Hypertropia (manifest vertical squint)
IOP	Intraocular pressure
IPD	Interpupillary distance
J1–J20	Test types (Jaeger) for testing reading vision
KP	Keratic precipitate
LP	Light perception
L Proj	Light projection
NLP	No light perception
NPC	Near point of convergence
OD (R, or RE)	Oculus dexter (right eye)
OS (L, or LE)	Oculus sinister (left eye)
OU	Oculi unitas (both eyes)
PD	Prism diopter
PH	Pinhole
PRRE	Pupils round, regular, and equal
S or Sph	Spherical lens
VA	Visual acuity

VER	Visual evoked response
X	Exophoria (latent divergent squint)
XT	Exotropia (manifest divergent squint)
+	Plus (convex) lens
–	Minus (concave) lens
	Combined with
∞	Infinity (6 meters [20 feet] or more distance)
°	Degree (measurement of strabismus angle)
	Prism diopter (PD)

Visual Acuity (VA)

Corrected distant visual acuity should be tested for each eye in turn, using a Snellen or logMAR (EDTRS) chart, annotated according to the distance at which each line can be read by a normal individual. It is traditionally measured at 20 feet (6 meters in Europe) or nearer if vision is poor, but other test distances may be used. Visual acuity is expressed as a fraction—the test distance over the figure assigned to the lowest line the patient can read. If the patient is unable to read the top line even when standing close to the chart, acuity is recorded as counting fingers (CF), hand movements (HM), perception of light (LP), or no light perception (NLP). A corrected acuity of less than 20/30 (6/9) is abnormal.

Near acuity is tested with a reduced Snellen chart or standardized reading test types. The patient must be wearing appropriate reading correction.

Visual Fields

Confrontation testing, preferably using a 5-mm red target, is valuable for rapid assessment of field defects (see illustration). Amsler charts are the easiest method of detecting central field abnormalities due to macular disease.

Pupils

The pupils are examined for absolute and relative size and reactions to both light and accommodation (see illustration). A large, poorly reacting pupil may be due to third nerve palsy, acute tonic pupil, iris damage caused by acute glaucoma, or pharmacologic mydriasis. A small pupil occurs in Horner syndrome, inflammatory adhesions between iris and lens (posterior synechiae), long-standing tonic pupil, or neurosyphilis (Argyll Robertson pupils). Physiologic anisocoria is a common cause of unequal pupils that react normally.

Fig.

Anatomic basis of the pupillary light reflex. The afferent visual pathways from the retina to the pretectal nuclei of the midbrain are represented by dashed lines, the efferent pupilloconstrictor pathways from the midbrain to the retinas by solid lines. Note that illumination of one eye results in bilateral pupillary constriction. (Reproduced, with permission from Simon RP, Aminoff MJ, Greenberg DA: *Clinical Neurology*, 4th ed. McGraw-Hill, 1999.)

A relative afferent pupillary defect, in which the pupillary light reaction is reduced when light is shined into the affected eye compared with the normal eye, generally indicates optic nerve disease. It is detected with the "swinging light test," in which the pupillary light reactions are compared as a bright light is moved from one eye to the other (see illustration).

Fig.

Relative afferent pupillary defect. (Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology*, 17th ed. McGraw-Hill, 2008.)

Extraocular Movements

Examination of extraocular movements begins with an assessment of whether the two eyes are correctly aligned. A misalignment of the visual axes under binocular viewing conditions is known as a manifest deviation **(tropia)**. A deviation only when binocular function is disrupted is known as a latent deviation **(phoria),** which is common among normal individuals. A manifest deviation may be apparent by comparing the relative positions of the corneal light reflexes. More reliable is the **cover test**, in which the deviated eye moves to take up fixation when the other eye is occluded. The correctional movement is in the direction opposite to that of the original manifest deviation. If there is no manifest deviation, any correctional movement that occurs to reestablish the normal alignment of the eyes as the occluder is removed **(uncover test)** and indicates a latent deviation.

Horizontal diplopia indicates dysfunction of the medial or lateral rectus muscles; vertical diplopia results from dysfunction of the superior or inferior recti or the obliques. The false outer image arises from the affected eye. If muscle contraction is impaired, the image separation will be greatest in its normal direction of action; if a muscle cannot relax, image separation will be greatest in the direction opposite to its normal action. For example, a paretic lateral rectus or a tethered medial rectus of the right eye will cause maximal image separation on looking to the right.

Nystagmus in the primary position is always abnormal. Minor degrees of nystagmus at the extremes of gaze are normal. Other forms of physiologic nystagmus include optokinetic nystagmus and nystagmus induced by rotation or caloric stimulation. Exaggerated gaze-evoked nystagmus may be due to drugs or posterior fossa disease.

Proptosis (Exophthalmos)

Proptosis is suspected when there is widening of the palpebral aperture, with exposure of sclera both superiorly and inferiorly. (Eyelid retraction causes more exposure superiorly than inferiorly.) By viewing from above while the patient is asked to look down and the upper lids are lifted by the examiner, a further estimate of the degree of proptosis can be made. Exophthalmometry provides objective assessment. In nonaxial proptosis, there is also horizontal or vertical displacement of the globe, indicating the presence of a mass lesion outside the extraocular muscle cone.

The most frequent cause of proptosis in adults is dysthyroid eye disease. Other causes include orbital cellulitis, tumors, and pseudotumor.

Ptosis

Ptosis is usually due to eyelid disease. Neurologic causes of ptosis include Horner syndrome, in which the pupil is constricted, and third nerve palsy, in which there are abnormalities of eye movements and the pupil may be dilated and react poorly to light. In myasthenia gravis, the pupils are normal and characteristically the ptosis is fatiguable.

Anterior Segment Examination

Although slit-lamp examination is more sensitive, examination with a flashlight and loupe usually provides sufficient information for initial assessment. Patterns of redness indicate the site of the problem. In conjunctivitis, it extends diffusely across the globe and the inner surface of the lids. Keratitis, intraocular inflammation, and acute glaucoma lead to predominantly circumcorneal injection. Episcleritis and scleritis cause localized or diffuse deep injection, which in the case of scleritis is associated with blue discoloration.

Focal lesions of the cornea due to infection or trauma can be differentiated from the diffuse corneal haze of acute glaucoma and from the cloudiness of the anterior chamber and perhaps hypopyon (white cells within the anterior chamber) of iritis. Instillation of fluorescein and examination with a blue light aid in detection of corneal epithelial defects (see photograph).

Fig.

Direct Ophthalmoscopy

Direct ophthalmoscopy, ideally following pupil dilation with tropicamide 0.5–1%, which rarely induces angle-closure glaucoma, is used for examining the retina. Assessment of the red reflex and clarity of fundal details indicate the degree of media opacity. Abnormalities may then be localized to the cornea, lens, or vitreous by variations of focus of the ophthalmoscope and use of parallax.

The optic disk is examined for swelling, pallor, and glaucomatous cupping. Macular lesions causing poor central vision are usually apparent. The retinal vessels are scrutinized for caliber and wall changes. Retinal hemorrhages, hard exudates, and cotton-wool spots are noted. In hospital patients, dilation should be noted in the record to avoid confusion on neurologic examination.

Ophthalmologic Referrals

Important causes of sudden visual loss in an uninflamed eye are vitreous hemorrhage, including due to proliferative diabetic retinopathy; retinal detachment; neovascular age-related macular degeneration; retinal vein occlusion; retinal artery occlusion; and anterior ischemic optic neuropathy, either possibly due to giant cell arteritis, and optic neuritis. All these conditions require urgent ophthalmologic consultation, but giant cell arteritis requires emergency treatment. Sudden loss of vision in an inflamed eye may be due to acute glaucoma or corneal ulcer, both of which require emergency treatment, or acute anterior uveitis, which requires urgent ophthalmologic assessment. Other emergencies include orbital cellulitis, gonococcal keratoconjunctivitis, and ocular trauma.

Patients with gradual loss of vision should also be referred. The principal causes are cataract, atrophic age-related macular degeneration, chronic glaucoma, diabetic maculopathy, chronic uveitis, and intraorbital and intracranial tumors.

Patients with diabetes must undergo at least annual examination for retinopathy, even in the absence of visual symptoms. Any patient with myopia should be warned of the increased risk of retinal detachment and made aware of the importance of reporting relevant symptoms. First-degree adult relatives of patients with glaucoma should undergo screening annually.

Refractive Errors

Refractive errors are the most common cause of reduced clarity of vision (visual acuity) and may be a readily treatable component of poor vision in patients with other diagnoses. In **emmetropia** (the normal state), objects at infinity are seen clearly with the unaccommodated eye. Objects nearer than infinity are seen with the aid of accommodation, which increases the refractive power of the lens. In **hyperopia**, objects at infinity are not seen clearly unless accommodation is used, and near objects may not be seen because accommodative capacity is finite. Hyperopia is corrected with plus (convex) lenses.

In **myopia**, the unaccommodated eye focuses on objects closer than infinity; the distance of such objects from the patient becomes progressively shorter with increasing myopia. Thus, the high myope is able to focus on very near objects without glasses. Objects beyond this distance cannot be seen without the aid of corrective (minus, concave) lenses. In **astigmatism**, the refractive errors in the horizontal and vertical axes differ. **Presbyopia** is the natural loss of accommodative capacity with age. Persons with emmetropia usually notice inability to focus on objects at a normal reading distance at about age 45. Persons with hyperopia experience symptoms at an earlier age. Presbyopia is corrected with plus lenses for near work.

Use of a pinhole will overcome most refractive errors and thus allows their identification as a cause of reduced visual acuity.

Contact Lenses

Contact lenses are used mostly for correction of refractive errors, for which they provide better optical correction than glasses, as well as for management of diseases of the cornea, conjunctiva, or lids. The major types of lenses are rigid (gas-permeable) and soft. Rigid lenses are more durable and easier to care for than soft lenses but are more difficult to tolerate.

Contact lens care includes cleaning and sterilization whenever the lenses are removed and removal of protein deposits as required. Sterilization is usually by chemical methods. For individuals developing reactions to preservatives in contact lens solutions, preservative-free systems are available. All contact lenses can be inserted in the morning and removed at night. Soft lenses are also available for extended wear. Disposable soft lenses to avoid the necessity for lens cleaning and sterilization are available for daily or extended wear.

The major risk from contact lens wear is bacterial, amebic, or fungal corneal infection, potentially a blinding condition. Such infections occur more commonly with soft lenses, particularly extended wear, for which there is at least a fivefold increase in risk of corneal ulceration compared with daily wear. Contact lens wearers should be made aware of the risks they face and ways to minimize them, such as avoiding extended-wear soft lenses and maintaining meticulous lens hygiene, including not using tap water or saliva for lens cleaning. Whenever there is ocular discomfort or redness, contact lenses should be removed. Ophthalmologic care should be sought if symptoms persist.

When to Refer

Any contact lens wearer with an acute painful red eye must be referred emergently to an ophthalmologist.

Surgical Correction

Various surgical techniques are available for the correction of refractive errors, particularly myopia. Laser corneal refractive surgery reshapes the mid-portion (stroma) of the cornea with an excimer laser. Laser assisted in situ keratomileusis (LASIK), including femtosecond laser assisted LASIK (IntraLASIK), and the surface ablation techniques epithelial LASIK (Epi-LASIK), laser epithelial keratomileusis (LASEK), and photorefractive keratectomy (PRK) differ according to how access to the stroma is achieved. LASIK is most commonly performed because postoperative visual recovery is rapid and there is little postoperative discomfort, but it is contraindicated if the cornea is relatively thin. Visual outcomes are impressive and many individuals seek treatment, more than 1 million people undergo LASIK each year in the United States. However, outcomes for individual cases are not completely predictable. Repeated treatment is required in up to 15% of patients and serious complications occur in up to 5%. Other refractive surgery techniques are extraction of the clear crystalline lens with insertion of a single vision, multifocal or accommodative intraocular lens, insertion of an intraocular lens without removal of the crystalline lens (phakic intraocular lens), intrastromal corneal ring segments (INTACS), and conductive keratoplasty (CK). Topical atropine and pirenzepine, a selective muscarinic antagonist, and rigid contact lens wear during sleep (orthokeratology) are also being investigated for myopia.

Ophthalmology. 2008 Dec;115(12):2301–13. [PMID: 18804868]

Hordeolum

Hordeolum is a common staphylococcal abscess that is characterized by a localized red, swollen, acutely tender area on the upper or lower lid (Plate 48). Internal hordeolum is a meibomian gland abscess that usually points onto the conjunctival surface of the lid; external hordeolum or sty is smaller and on the margin (see photograph).

Plate 48.

External hordeolum (*black arrow*) and chalazion (*white arrow*), which developed from an internal hordeolum (courtesy of Richard P. Usatine, MD; Used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw Hill, 2009.)

Fig.

Internal hordeolum, left upper eyelid, pointing on skin side. This should be opened by a horizontal skin incision. (Courtesy of A Rosenberg. Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology*, 17th ed. McGraw-Hill, 2008.)

Warm compresses are helpful. Incision may be indicated if resolution does not begin within 48 hours. An antibiotic ointment (bacitracin or erythromycin) applied to the eyelid every 3 hours may be beneficial during the acute stage. Internal hordeolum may lead to generalized cellulitis of the lid.

Chalazion

Chalazion is a common granulomatous inflammation of a meibomian gland that may follow an internal hordeolum. It is characterized by a hard, nontender swelling on the upper or lower lid with redness and swelling of the adjacent conjunctiva. If the chalazion is large enough to impress the cornea, vision will be distorted. Treatment is usually by incision and curettage (see photograph) but corticosteroid injection may also be effective.

Blepharitis

Blepharitis is a common chronic bilateral inflammatory condition of the lid margins. **Anterior blepharitis** involves the eyelid skin, eyelashes, and associated glands. It may be ulcerative, because of infection by staphylococci, or seborrheic in association with seborrhea of the scalp, brows, and ears. **Posterior blepharitis** results from inflammation of the meibomian glands. There may be bacterial infection, particularly with staphylococci, or primary glandular dysfunction, in which there is a strong association with acne rosacea.

Clinical Findings

Symptoms are irritation, burning, and itching. In anterior blepharitis, the eyes are "red-rimmed," and scales or granulations can be seen clinging to the lashes. In posterior blepharitis, the lid margins are hyperemic with telangiectasias; the meibomian glands and their orifices are inflamed, with dilation of the glands, plugging of the orifices, and abnormal secretions. The lid margin is frequently rolled inward to produce a mild entropion, and the tears may be frothy or abnormally greasy.

Blepharitis is a common cause of recurrent conjunctivitis. Both anterior and, more particularly, posterior blepharitis may be complicated by hordeola or chalazions; abnormal lid or lash positions, producing trichiasis; epithelial keratitis of the lower third of the cornea; marginal corneal infiltrates; and inferior corneal vascularization and thinning.

Treatment

Anterior blepharitis is usually controlled by cleanliness of the lid margins, eyebrows, and scalp. Scales should be removed from the lids daily with a hot wash cloth or a damp cotton applicator and baby shampoo. In acute exacerbations, an antistaphylococcal antibiotic eye ointment such as bacitracin or erythromycin is applied daily to the lid margins. Antibiotic sensitivity studies may be helpful in severe cases.

In mild posterior blepharitis, regular meibomian gland expression may be sufficient to control symptoms. Inflammation of the conjunctiva and cornea indicates a need for more active treatment, including long-term low-dose oral antibiotic therapy, usually with tetracycline (250 mg twice daily), doxycycline (100 mg daily), minocycline (50–100 mg daily) or erythromycin (250 mg three times daily), and possibly short-term topical corticosteroids, eg, prednisolone, 0.125% twice daily. Topical therapy with antibiotics such as ciprofloxacin 0.3% ophthalmic solution twice daily may be helpful but should be restricted to short courses.

Jackson WB. Blepharitis: current strategies for diagnosis and management. Can J Ophthalmol. 2008 Apr;43(2):170–9. [PMID: 18347619]

Entropion & Ectropion

Entropion (inward turning of usually the lower lid) occurs occasionally in older people as a result of degeneration of the lid fascia, or may follow extensive scarring of the conjunctiva and tarsus (see photograph). Surgery is indicated if the lashes rub on the cornea. Botulinum toxin injections may also be used for temporary correction of the involutional lower eyelid entropion of older people.

Fig.

Entropion. (Courtesy of M Quickert. Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology*, 17th ed. McGraw-Hill, 2008.)

Ectropion (outward turning of the lower lid) is common with advanced age (see photograph). Surgery is indicated if there is excessive tearing, exposure keratitis, or a cosmetic problem.

Fig.

Ectropion. (Courtesy of M Quickert. Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology*, 17th ed. McGraw-Hill, 2008.)

Tumors

Basal cell carcinoma, squamous cell carcinoma, meibomian gland carcinoma, and malignant melanoma are the common cancers of the skin of the eyelids. Surgery for any lesion involving the lid margin should be performed by an ophthalmologist or suitably trained plastic surgeon to avoid deformity of the lid. Otherwise, small lesions can often be excised by the nonophthalmologist. Histopathologic examination of eyelid tumors should be routine, since 2% of lesions thought to be benign clinically are found to be malignant. The Mohs technique of intraoperative examination of excised tissue is particularly valuable in ensuring complete excision so that the risk of recurrence is reduced.

Dacryocystitis

Dacryocystitis is infection of the lacrimal sac due to obstruction of the nasolacrimal system. It may be acute or chronic and occurs most often in infants and in persons over 40 years. It is usually unilateral.

The usual infectious organisms are *Staphylococcus aureus* and -hemolytic streptococci in acute dacryocystitis and *Staphylococcus epidermidis*, anaerobic streptococci, or *Candida albicans* in chronic dacryocystitis.

Acute dacryocystitis is characterized by pain, swelling, tenderness, and redness in the tear sac area; purulent material may be expressed (see photograph). In chronic dacryocystitis, tearing and discharge are the principal signs, and mucus or pus may also be expressed.

Fig.
Acute dacryocystitis. (Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology*, 17th ed. McGraw-Hill, 2008.)

Acute dacryocystitis responds well to systemic antibiotic therapy. Surgical relief of the underlying obstruction is usually done electively but may be performed urgently in acute cases. The chronic form may be kept latent with antibiotics, but relief of the obstruction is the only cure. In adults, the standard procedure for obstruction of the lacrimal drainage system is dacryocystorhinostomy, which involves surgical exploration of the lacrimal sac and formation of a fistula into the nasal cavity. Laser-assisted endoscopic dacryocystorhinostomy and balloon dilation or probing of the nasolacrimal system are alternatives. Congenital nasolacrimal duct obstruction is common and often resolves spontaneously but, if necessary, can be treated by probing of the nasolacrimal system, for example.

Conjunctivitis: Introduction

Conjunctivitis is the most common eye disease. It may be acute or chronic. Most cases are due to viral or bacterial (including gonococcal and chlamydial) infection. Other causes include keratoconjunctivitis sicca, allergy, chemical irritants, and deliberate self-harm. The mode of transmission of infectious conjunctivitis is usually direct contact via fingers, towels, handkerchiefs, etc, to the fellow eye or to other persons. It may be through contaminated eye drops.

Conjunctivitis must be differentiated from acute uveitis, acute glaucoma, and corneal disorders (Table 7–1).

Viral Conjunctivitis

One of the most common causes of viral conjunctivitis is adenovirus type 3 (see photograph). Conjunctivitis due to this agent is usually associated with pharyngitis, fever, malaise, and preauricular adenopathy (pharyngoconjunctival fever). Locally, the palpebral conjunctiva is red, and there is a copious watery discharge and scanty exudate. Children are more often affected than adults, and contaminated swimming pools are sometimes the source of infection. The disease usually lasts 10 days. Epidemic keratoconjunctivitis is caused by adenovirus types 8, 19, 29, and 37. It is more likely to be complicated by visual loss due to corneal subepithelial infiltrates. The disease lasts at least 2 weeks.

Fig.

Acute follicular conjunctivitis due to adenovirus type 3. (Courtesy of P Thygeson. Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology*, 17th ed. McGraw-Hill, 2008.)

Topical sulfonamides prevent secondary bacterial infection and cold compresses reduce the discomfort of the associated lid edema.

Rutala WA et al. Efficacy of hospital germicides against adenovirus 8, a common cause of epidemic keratoconjunctivitis in health care facilities. Antimicrob Agents Chemother. 2006 Apr;50(4):1419-24. [PMID: 16569860]

Bacterial Conjunctivitis

The organisms isolated most commonly in bacterial conjunctivitis are staphylococci, streptococci (particularly *S pneumoniae*), *Haemophilus* species, *Pseudomonas*, and *Moraxella*. All may produce a copious purulent discharge. There is no blurring of vision and only mild discomfort. In severe cases, examination of stained conjunctival scrapings and cultures is recommended.

The disease is usually self-limited, lasting about 10–14 days if untreated. Topical sulfonamide (eg, sulfacetamide, 10% ophthalmic solution or ointment three times a day) will usually clear the infection in 2–3 days but the need for antibacterial therapy is disputed. Povidone-iodine may also be effective. The use of topical fluoroquinolones is rarely justified for treatment of a generally self-limiting, benign infection.

Gonococcal Conjunctivitis

Gonococcal conjunctivitis, usually acquired through contact with infected genital secretions, typically causes copious purulent discharge (see photograph); (eFigure 7–3: photograph). It is an ophthalmologic emergency because corneal involvement may rapidly lead to perforation. The diagnosis should be confirmed by stained smear and culture of the discharge. A single 1-g dose of intramuscular ceftriaxone is usually adequate. Topical antibiotics such as erythromycin and bacitracin may be added. Other sexually transmitted diseases, including chlamydiosis, syphilis, and HIV infection, should be considered.

Chlamydial Keratoconjunctivitis

Trachoma

Trachoma is a major cause of blindness worldwide. Recurrent episodes of infection in childhood manifest as bilateral follicular conjunctivitis, epithelial keratitis, and corneal vascularization (pannus). Cicatrization of the tarsal conjunctiva leads to entropion and trichiasis in adulthood, with secondary central corneal scarring. (see photograph); (see photograph); (see photograph).

Fig.

Fig.

Advanced trachoma following corneal ulceration and scarring. (Courtesy of P Thygeson.)

Fig.

Ptosis with an S-shaped curve of lids associated with chronic trachoma. (Courtesy of P Thygeson.)

Immunologic tests or polymerase chain reaction on conjunctival samples will confirm the diagnosis but treatment should be started on the basis of clinical findings. Single-dose therapy with oral azithromycin, 20 mg/kg, is effective. Alternatively, oral tetracycline or erythromycin, 250 mg four times a day, or doxycycline, 100 mg twice a day, is given for 3–4 weeks. Local treatment is not necessary. Surgical treatment includes correction of eyelid deformities and corneal transplantation.

Yorston D et al. Interventions for trachoma trichiasis. Cochrane Database Syst Rev. 2006 Jul 19;3:CD004008. [PMID: 16856026]

Inclusion conjunctivitis

The agent of inclusion conjunctivitis is a common cause of genital tract disease in adults. The eye is usually involved following contact with genital secretions. The disease starts with acute redness, discharge, and irritation. The eye findings consist of follicular conjunctivitis with mild keratitis (see photograph). A nontender preauricular lymph node can often be palpated. Healing usually leaves no sequelae. Diagnosis can be rapidly confirmed by immunologic tests or polymerase chain reaction on conjunctival samples. Treatment is with oral tetracycline or erythromycin, 500 mg four times a day, or doxycycline, 100 mg twice a day, for 1–2 weeks. Single-dose therapy with azithromycin, 1 g, may also be effective. Before treatment, all cases should be assessed for genital tract infection so that management can be adjusted accordingly, and other venereal diseases sought.

Dry Eyes (Keratoconjunctivitis Sicca)

This is a common disorder, particularly in older women. Hypofunction of the lacrimal glands, causing loss of the aqueous component of tears, may be due to aging, hereditary disorders, systemic disease (eg, Sjögren syndrome), or systemic and topical drugs. Excessive evaporation of tears may be due to environmental factors (eg, a hot, dry, or windy climate) or abnormalities of the lipid component of the tear film, as in blepharitis. Mucin deficiency may be due to malnutrition, infection, burns, or drugs.

Clinical Findings

The patient complains of dryness, redness, or a scratchy feeling of the eyes. In severe cases there is persistent marked discomfort, with photophobia, difficulty in moving the eyelids, and often excessive mucus secretion. In many cases, inspection reveals no abnormality, but on slitlamp examination there are subtle abnormalities of tear film stability and reduced volume of the tear film meniscus along the lower lid. In more severe cases, damaged corneal and conjunctival cells stain with 1% rose bengal (see photograph), which is to be avoided in severe cases because of the intense pain. In the most severe cases there is marked conjunctival injection, loss of the normal conjunctival and corneal luster, epithelial keratitis that may progress to frank ulceration, and mucous strands. Schirmer test, which measures the rate of production of the aqueous component of tears, may be helpful.

Rose bengal staining of corneal and conjunctival cells in a 54-year-old woman with keratoconjunctivitis sicca. (Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General*

Ophthalmology, 17th ed. McGraw-Hill, 2008.)

Treatment

Aqueous deficiency can be treated by replacement of the aqueous component of tears with various types of artificial tears. The simplest preparations are physiologic (0.9%) or hypo-osmotic (0.45%) solutions of sodium chloride. Balanced salt solution is more physiologic but also more expensive. All of these drop preparations can be used as frequently as every half-hour, but in most cases are needed only three or four times a day. More prolonged duration of action can be achieved with drop preparations containing methylcellulose (eg, Isopto Plain), polyvinyl alcohol (eg, Liquifilm Tears or HypoTears), or polyacrylic acid (carbomers) (eg, GelTears or Viscotears) or by using petrolatum ointment (Lacri-Lube). Such mucomimetics are particularly indicated when there is mucin deficiency. If there is tenacious mucus, mucolytic agents (eg, acetylcysteine, 20% six times daily) may be helpful. Autologous serum eye drops are used in severe dry eye. The presence of ocular surface and lacrimal gland inflammation in dry eyes has prompted the use of anti-inflammatory agents, such as topical cyclosporine.

Lacrimal punctal occlusion by canalicular plugs or surgery is useful in severe cases. Blepharitis is treated as described above. Associated blepharospasm may benefit from botulinum toxin injections.

Artificial tear preparations are generally very safe and without side effects. However, the preservatives necessary to maintain their sterility are potentially toxic and allergenic and may cause keratitis and cicatrizing conjunctivitis in frequent users. Furthermore, the development of such reactions may be misinterpreted by both the patient and the doctor as a worsening of the dry eye state requiring more frequent use of the artificial tears and leading in turn to further deterioration, rather than being recognized as a need to change to a preservative-free preparation.

Allergic Eye Disease

Allergic eye disease takes a number of different forms but all are expressions of atopy, which may also manifest as atopic asthma, atopic dermatitis, or allergic rhinitis.

Clinical Findings

Symptoms include itching, tearing, redness, stringy discharge and, occasionally, photophobia and visual loss.

Allergic conjunctivitis is a benign disease, occurring usually in late childhood and early adulthood. It may be seasonal (hay fever), developing usually during the spring or summer, or perennial. Clinical signs are limited to conjunctival hyperemia and edema (chemosis), the latter at times being marked and sudden in onset. **Vernal keratoconjunctivitis** also tends to occur in late childhood and early adulthood. It is usually seasonal, with a predilection for the spring. Large "cobblestone" papillae are noted on the upper tarsal conjunctiva (see photograph). There may be lymphoid follicles at the limbus. **Atopic keratoconjunctivitis** is a more chronic disorder of adulthood. Both the upper and the lower tarsal conjunctivas exhibit a fine papillary conjunctivitis with fibrosis, resulting in forniceal shortening and entropion with trichiasis. Staphylococcal blepharitis is a complicating factor. Corneal involvement, including refractory ulceration, is frequent during exacerbations of both vernal and atopic keratoconjunctivitis. The latter may be complicated by herpes simplex keratitis.

Treatment

Mild and Moderately Severe Allergic Eye Disease

Apply a topical histamine H_1-receptor antagonist, such as levocabastine hydrochloride 0.05% or emedastine difumarate 0.05%, or ketorolac tromethamine 0.5%, a nonsteroidal anti-inflammatory agent, four times daily. Ketotifen 0.025%, which has histamine H_1-receptor antagonist, mast cell stabilizer, and eosinophil inhibitor activity, is applied two to four times daily; olopatadine, 0.2% once daily or 0.1% twice daily, azelastine 0.05% twice daily, and epinastine 0.05% twice daily reduce symptoms by a similar mechanism. Topical mast cell stabilizers, such as cromolyn sodium 4% or lodoxamide tromethamine 0.1%, applied four times daily, or nedocromil sodium 2%, applied twice daily, produce longer-term prophylaxis but the therapeutic response may be delayed. Topical vasoconstrictors and antihistamines are of limited efficacy in allergic eye disease and may produce rebound hyperemia and follicular conjunctivitis. Systemic antihistamines may be useful in prolonged atopic keratoconjunctivitis. In allergic conjunctivitis, specific allergens may be identifiable and thus avoidable. In vernal keratoconjunctivitis, a cooler climate often provides significant benefit.

Acute Exacerbations and Severe Allergic Eye Disease

Topical corticosteroids are essential to the control of acute exacerbations of both vernal and atopic keratoconjunctivitis. Corticosteroid-induced side effects, including cataracts, glaucoma, and exacerbation of herpes simplex keratitis, are major problems but may be attenuated by the ester corticosteroid, loteprednol 0.5%. Topical cyclosporine is also effective. Systemic corticosteroid therapy and even plasmapheresis may be required in severe atopic keratoconjunctivitis.

Pinguecula & Pterygium

Pinguecula is a yellow elevated conjunctival nodule, more commonly on the nasal side, in the area of the palpebral fissure. It is common in persons over age 35 years. Pterygium is a fleshy, triangular encroachment of the conjunctiva onto the nasal side of the cornea and is usually associated with constant exposure to wind, sun, sand, and dust (Plate 49); (see photograph). Pinguecula and pterygium are often bilateral.

Plate 49.

Fig.

Pterygium encroaching on the cornea.

Pingueculae rarely grow but may become inflamed (pingueculitis). Pterygia become inflamed and may grow. No treatment is usually required for inflammation of pinguecula or pterygium, but artificial tears are often beneficial, and short courses of topical nonsteroidal anti-inflammatory agents or weak corticosteroids (prednisolone, 0.125% three times a day) may be necessary.

The indications for excision of pterygium are growth that threatens vision by approaching the visual axis, marked induced astigmatism, or severe ocular irritation. Recurrence is common and often more aggressive than the primary lesion.

Ang LP et al. Current concepts and techniques in pterygium treatment. Curr Opin Ophthalmol. 2007 Jul;18(4):308–13. [PMID: 17568207]

Corneal Ulcer: Introduction

Corneal ulcers are most commonly due to infection by bacteria, viruses, fungi, or amebas. Noninfectious causes—all of which may be complicated by infection—include neurotrophic keratitis (resulting from loss of corneal sensation), exposure keratitis (due to inadequate eyelid closure), severe dry eyes, severe allergic eye disease, and various inflammatory disorders that may be purely ocular or part of a systemic vasculitis. Delayed or ineffective treatment of corneal infection may lead to devastating consequences with corneal scarring or intraocular infection. Prompt referral is essential.

Patients complain of pain, photophobia, tearing, and reduced vision. The eye is red, with predominantly circumcorneal injection, and there may be purulent or watery discharge. The corneal appearance varies according to the organisms involved.

When to Refer

Any patient with an acute painful red eye and corneal abnormality should be referred emergently to an ophthalmologist.

Dahlgren MA et al. The clinical diagnosis of microbial keratitis. Am J Ophthalmol. 2007 Jun;143(6):940–4. [PMID: 17408586]

Thomas PA et al. Infectious keratitis. Curr Opin Infect Dis. 2007 Apr;20(20):129–41. [PMID: 17496570]

Bacterial Keratitis

Bacterial keratitis usually pursues an aggressive course. Precipitating factors include contact lens wear—especially overnight wear—and corneal trauma, including refractive surgery. The pathogens most commonly isolated are *Pseudomonas aeruginosa*, *Pneumococcus*, *Moraxella* species, and staphylococci. The cornea is hazy, with a central ulcer and adjacent stromal abscess (see photograph); (see photograph); (see photograph). Hypopyon is often present (eFigure 7–4: photograph). The ulcer is scraped to recover material for Gram stain and culture prior to starting treatment with high-concentration topical antibiotics applied hourly day and night for at least the first 48 hours. Fluoroquinolones such as levofloxacin 0.5%, ofloxacin 0.3%, norfloxacin 0.3%, or ciprofloxacin 0.3% are commonly used as first-line agents as long as local prevalence of resistant organisms is low. The fourth-generation fluoroquinolones (moxifloxacin 0.5% and gatifloxacin 0.3% [not available in the United States]), are also active against mycobacteria but otherwise may not be preferable. Gram-positive cocci can also be treated with a cephalosporin such as cefazolin, 100 mg/mL; and gram-negative bacilli can be treated with an aminoglycoside such as tobramycin, 15 mg/mL. If no organisms are seen on Gram stain, these two agents can be used together in areas where resistance to fluoroquinolones is common. Adjunctive topical corticosteroid therapy should only be prescribed by an ophthalmologist.

Herpes Simplex Keratitis

Herpes simplex keratitis is an important cause of ocular morbidity (see photograph); (see photograph). The ability of the virus to colonize the trigeminal ganglion leads to recurrences precipitated by fever, excessive exposure to sunlight, or immunodeficiency.

Fig.

Primary ocular herpes. (Courtesy of HB Ostler. Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology*, 17th ed. McGraw-Hill, 2008.)

Fig.

Corneal scar caused by recurrent herpes simplex keratitis. (Courtesy of A Rosenberg. Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology*, 17th ed. McGraw-Hill, 2008.)

The dendritic (branching) ulcer is the most characteristic manifestation (see photograph). More extensive ("geographic") ulcers also occur, particularly if topical corticosteroids have been used. These ulcers are most easily seen after instillation of fluorescein and examination with a blue light. Such epithelial disease in itself does not lead to corneal scarring. It responds well to simple debridement and patching. More rapid healing can be achieved by the addition of topical antivirals such as trifluridine drops or acyclovir ointment. Long-term oral acyclovir reduces the rate of recurrent epithelial disease, for which topical corticosteroids must not be used.

Fig.

Dendritic figures seen in herpes simplex keratitis. (Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology*, 17th ed. McGraw-Hill, 2008.)

Stromal herpes simplex keratitis produces increasingly severe corneal opacity with each recurrence. Topical antivirals alone are insufficient to control stromal disease. Thus, topical corticosteroids are used in combination, but steroid dependence is a common consequence. Corticosteroids may also enhance viral replication, exacerbating epithelial disease. Oral acyclovir, 200–400 mg five times a day, is often helpful in the treatment of severe herpetic keratitis and for prophylaxis against recurrences, particularly in atopic or HIV-infected individuals. Severe stromal scarring may require corneal grafting, but the overall outcome is relatively poor. **Caution:** For patients with known or possible herpetic disease, topical corticosteroids should be prescribed only with ophthalmologic supervision.

When to Refer

Any patient with a history of herpes simplex keratitis and an acute red eye should be referred urgently to an ophthalmologist.

Herpes Zoster Ophthalmicus

Herpes zoster frequently involves the ophthalmic division of the trigeminal nerve. It presents with malaise, fever, headache, and periorbital burning and itching. These symptoms may precede the eruption by a day or more. The rash is initially vesicular, quickly becoming pustular and then crusting. Involvement of the tip of the nose or the lid margins predicts involvement of the eye. Ocular signs include conjunctivitis, keratitis, episcleritis, and anterior uveitis, often with elevated intraocular pressure. Recurrent anterior segment inflammation, neurotrophic keratitis, and posterior subcapsular cataract are long-term complications. Optic neuropathy, cranial nerve palsies, acute retinal necrosis, and cerebral angiitis are infrequent problems in the acute stage. HIV infection is an important risk factor for herpes zoster ophthalmicus and increases the likelihood of complications.

High-dose oral acyclovir (800 mg five times a day), valacyclovir (1 g three times a day), or famciclovir (250–500 mg three times a day) started within 72 hours after the appearance of the rash reduces the incidence of ocular complications but not necessarily of postherpetic neuralgia. Anterior uveitis requires treatment with topical corticosteroids and cycloplegics. Neurotrophic keratitis is an important cause of long-term morbidity.

When to Refer

Any patient with herpes zoster ophthalmicus and ocular symptoms or signs should be referred urgently to an ophthalmologist.

Fungal Keratitis

Fungal keratitis tends to occur after corneal injury involving plant material or in an agricultural setting, in eyes with chronic ocular surface disease, and increasingly in contact lens wearers. It is usually an indolent process, with the cornea characteristically having multiple stromal abscesses and relatively little epithelial loss (see photograph). Intraocular infection is common. Corneal scrapings are cultured on media suitable for fungi whenever the history or corneal appearance is suggestive of fungal disease. Diagnosis is often delayed and treatment is difficult. Natamycin and amphotericin are the most commonly used topical agents. Systemic imidazoles may be helpful. Corneal grafting is often required.

Acanthamoeba Keratitis

Acanthamoeba infection is an important cause of keratitis in contact lens wearers. Although severe pain with perineural and ring infiltrates in the corneal stroma is characteristic, earlier forms with changes confined to the corneal epithelium are identifiable. Diagnosis is often delayed but is facilitated by confocal microscopy. Culture requires specialized media. Treatment is hampered by the organism's ability to encyst within the corneal stroma. Various agents have been used, principally biguanides and diamidines. Epithelial debridement may be useful in early infections. Corneal grafting may be required in the acute stage to arrest the progression of infection or after resolution to restore vision. Systemic immunosuppression may be needed if there is scleral involvement.

Acute Angle-Closure Glaucoma

Essentials of Diagnosis

- Older age group, particularly hyperopes, Inuits, and Asians.
- Rapid onset of severe pain and profound visual loss with "halos around lights."
- Red eye, steamy cornea, dilated pupil.
- Hard eye to palpation.

General Considerations

Primary acute angle-closure glaucoma occurs only with closure of a preexisting narrow anterior chamber angle, found in older age groups (owing to enlargement of the lens), hyperopes, Inuits, and Asians. The value of prophylactic laser therapy in high-risk populations is being assessed. In the United States, about 1% of people over age 35 years have narrow anterior chamber angles, but acute glaucoma rarely develops and prophylactic therapy is not generally indicated. Angle closure may be precipitated by pupillary dilation and thus can occur from sitting in a darkened theater, at times of stress or, rarely, from pharmacologic mydriasis (see Precautions in Management of Ocular Disorders, below). Anticholinergic or sympathomimetic agents (eg, nebulized bronchodilators, atropine for preoperative medication, antidepressants, nasal decongestants, or tocolytics) are also causes. Secondary acute angle-closure glaucoma may be observed with anterior uveitis, dislocation of the lens, or topiramate therapy. Symptoms are the same as in primary acute angle-closure glaucoma, but differentiation is important because of differences in management. Chronic angle-closure glaucoma is particularly common in eastern Asia. It presents in the same way as open-angle glaucoma (see below).

Clinical Findings

Patients with acute glaucoma usually seek treatment immediately because of extreme pain and blurred vision, though there are subacute cases. The blurred vision is associated with halos around lights. Nausea and abdominal pain may occur. The eye is red, the cornea steamy, and the pupil moderately dilated and nonreactive to light. Intraocular pressure is usually over 50 mm Hg, producing a hard eye on palpation.

Differential Diagnosis

Acute glaucoma must be differentiated from conjunctivitis, acute uveitis, and corneal disorders (Table 7–1).

Treatment

Primary

Initial treatment in primary angle-closure glaucoma is control of intraocular pressure. A single 500-mg intravenous dose of acetazolamide, followed by 250 mg orally four times a day, is usually sufficient. Osmotic diuretics such as oral glycerol and intravenous urea or mannitol—the dosage of all three being 1–2 g/kg—may be necessary if there is no response to acetazolamide. Laser therapy to the peripheral iris (iridoplasty) or anterior chamber paracentesis is also effective. Once the intraocular pressure has started to fall, topical 4% pilocarpine, 1 drop every 15 minutes for 1 hour and then four times a day, is used to reverse the underlying angle closure. The definitive treatment is laser peripheral iridotomy or surgical peripheral iridectomy (see photograph), which should also be performed prophylactically on the fellow eye. Cataract extraction is a possible alternative. If it is not possible to control the intraocular pressure medically, glaucoma drainage surgery as for uncontrolled open-angle glaucoma (see below) may be required.

Fig.

Surgical peripheral iridectomy.

Secondary

In secondary acute angle-closure glaucoma, systemic acetazolamide is also used, with or without osmotic agents. Further treatment is determined by the cause.

Prognosis

Untreated acute angle-closure glaucoma results in severe and permanent visual loss within 2–5 days after onset of symptoms. Affected patients need to be observed for development of chronic glaucoma.

When to Refer

Any patient with suspected acute angle-closure glaucoma must be referred emergently to an ophthalmologist.

Lam DS et al. Current approaches to the management of acute primary angle closure. Curr Opin Ophthalmol. 2007 Mar;18(2):146–51. [PMID: 17301617]

Chronic Glaucoma

Essentials of Diagnosis

- No symptoms in early stages.
- Insidious progressive bilateral loss of peripheral vision, resulting in tunnel vision but preserved visual acuities.
- Pathologic cupping of the optic disks.
- Usually associated with persistent elevation of intraocular pressure.

General Considerations

Chronic glaucoma is characterized by gradually progressive excavation ("cupping") (eFigure 7–5: funduscopy) and pallor of the optic disk with loss of vision progressing from slight constriction of the peripheral fields to complete blindness. In chronic open-angle glaucoma, primary or secondary, the intraocular pressure is elevated due to reduced drainage of aqueous fluid through the trabecular meshwork. In chronic angle-closure glaucoma, flow of aqueous fluid into the anterior chamber angle is obstructed. In normal-tension glaucoma, intraocular pressure is not elevated but the same pattern of optic nerve damage occurs, probably due to vascular insufficiency.

eFigure 7–5.

Asymmetric optic disk cupping in glaucoma.

Primary open-angle glaucoma is bilateral. There is an increased prevalence in first-degree relatives of affected individuals and in diabetic patients. In blacks, it is more frequent, occurs at an earlier age, and results in more severe optic nerve damage. Secondary open-angle glaucoma may result from uveitis; ocular trauma; or corticosteroid therapy, whether it be topical, systemic, inhaled, or administered by nasal spray.

In the United States, it is estimated that 2% of people over 40 years of age have glaucoma, affecting more than 2 million individuals and being three times more prevalent in blacks. At least 25% of cases are undetected. Over 90% of cases are of the open-angle type, either primary open-angle or normal-tension glaucoma. Worldwide, about 50% of all cases of glaucoma are due to acute (see above) or chronic angle closure due to the very high prevalence of angle closure in Asians.

Clinical Findings

Because initially there are no symptoms, chronic glaucoma is often suspected at a routine eye test. Diagnosis requires consistent and reproducible abnormalities in at least two of three parameters—optic disk, visual field, and intraocular pressure. Optic disk cupping is identified as an absolute increase or an asymmetry between the two eyes of the ratio of the diameter of the optic cup to the diameter of the whole optic disk (cup-disk ratio, Plates 50 and 51). (Cup-disk ratio of greater than 0.5 or asymmetry of cup-disk ratio of 0.2 or more is suggestive.) (See funduscopy.) Visual field abnormalities initially develop in the paracentral region, followed by constriction of the peripheral visual field. Central vision remains good until late in the disease. The normal range of intraocular pressure is 10–21 mm Hg.

(Courtesy of S Mettier Jr. Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology*, 16th ed. McGraw-Hill, 2004.)

In many individuals, elevated intraocular pressure is not associated with optic disk or visual field abnormalities. These persons with **ocular hypertension** are at increased risk for glaucoma. Treatment to reduce intraocular pressure is justified if there is a moderate to high risk, determined by several factors, including age, optic disk appearance, level of intraocular pressure, and corneal thickness. A significant proportion of eyes with primary open-angle glaucoma have normal intraocular pressure when it is first measured, and only repeated measurements identify the abnormally high pressure. In normal-tension glaucoma, intraocular pressure is always within the normal range despite repeated measurement.

There are many other causes of optic disk abnormalities or visual field changes that mimic glaucoma, and visual field testing may prove unreliable in some patients, particularly in the older age group. Taken together, these factors mean that the diagnosis of glaucoma is not always straightforward, hampering the effectiveness of screening programs.

Prevention

All persons over age 40 years should have intraocular pressure measurement and optic disk examination every 2–5 years. In persons with diabetes and in individuals with a family history of glaucoma, annual examination is indicated. Regular ophthalmic screening should be considered in patients taking long-term oral or combined intranasal and inhaled corticosteroid therapy.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Treatment

Medications

The prostaglandin analogs (latanoprost 0.005%, bimatoprost 0.03%, and travoprost 0.004% once daily at night, and unoprostone 0.15% twice daily) are commonly used as first-line therapy because of their efficacy, their lack of systemic side effects, as well as the convenience of once-daily dosing of latanoprost, bimatoprost, and travoprost. All may produce conjunctival hyperemia, permanent darkening of the iris and eyebrow color, and increased eyelash growth. Latanoprost has been associated with reactivation of uveitis and macular edema.

Topical -adrenergic blocking agents such as timolol 0.25% or 0.5%, carteolol 1%, levobunolol 0.5%, and metipranolol 0.3% solutions twice daily or timolol 0.5% gel once daily may be used alone or in combination with a prostaglandin analog. They are contraindicated in patients with reactive airway disease or heart failure. Betaxolol, 0.25% or 0.5%, a -receptor selective blocking agent, is theoretically safer in reactive airway disease but less effective at reducing intraocular pressure. Brimonidine 0.2%, a selective $_2$-agonist, and dorzolamide 2% or brinzolamide 1%, topical carbonic anhydrase inhibitors, also can be used in addition to a prostaglandin analog or a -blocker (twice daily) or as initial therapy when prostaglandin analogs and -blockers are contraindicated (brimonidine twice daily, dorzolamide and brinzolamide three times daily). Both are associated with allergic reactions. Combination drops Xalacom (latanoprost 0.005% and timolol 0.5%), Ganfort (bimatoprost 0.03% and timolol 0.5%), and DuoTrav (travoprost 0.004% and timolol 0.5%), each used once daily, and Cosopt (dorzolamide 2% and timolol 0.5%) and Combigan (brimonidine 0.2% and timolol 0.5%), each used twice daily improve compliance when multiple medications are required.

Apraclonidine, 0.5–1%, another $_2$-agonist, can be used three times a day to postpone the need for surgery in patients receiving maximal medical therapy, but long-term use is limited by drug reactions. It is more commonly used to control acute rises in intraocular pressure such as after laser therapy. Pilocarpine 1–4%, epinephrine, 0.5–1%, and the prodrug dipivefrin, 0.1%, are rarely used because of adverse effects. Oral carbonic anhydrase inhibitors (eg, acetazolamide) may still be used on a long-term basis if topical therapy is inadequate and surgical or laser therapy is inappropriate.

Laser Therapy and Surgery

Laser trabeculoplasty is used as an adjunct to topical therapy to defer surgery and is also advocated as primary treatment. Surgery is generally undertaken when intraocular pressure is inadequately controlled by medical and laser therapy, but it may also be used as primary treatment. Trabeculectomy remains the standard procedure. Adjunctive treatment with subconjunctival mitomycin or fluorouracil is used perioperatively or postoperatively in difficult cases. Viscocanalostomy and deep sclerectomy with collagen implant—two alternative procedures that avoid a full-thickness incision into the eye—may prove to be as effective as trabeculectomy but are more difficult to perform.

In chronic angle-closure glaucoma, laser peripheral iridotomy or surgical peripheral iridectomy may be helpful.

Prognosis

Untreated chronic glaucoma that begins at age 40–45 years will probably cause complete blindness by age 60–65. Early diagnosis and treatment can preserve useful vision throughout life. In primary open-angle glaucoma—and if treatment is required in ocular hypertension—the aim is to reduce intraocular pressure to a level that will adequately reduce progression of visual field loss. In eyes with marked visual field or optic disk changes, intraocular pressure must be reduced to less than 16 mm Hg. In normal-tension glaucoma with progressive visual field loss, it is necessary to achieve even lower intraocular pressure such that surgery is often required.

When to Refer

All patients with suspected chronic glaucoma should be referred to an ophthalmologist.

Uveitis

Essentials of Diagnosis

- Usually immunologic but possibly infective or neoplastic.
- Acute nongranulomatous anterior uveitis: pain, redness, photophobia, and visual loss.
- Granulomatous anterior uveitis: blurred vision in a mildly inflamed eye.
- Posterior uveitis: gradual loss of vision in a quiet eye.

General Considerations

Intraocular inflammation (uveitis) is classified into acute or chronic, and nongranulomatous or granulomatous according to the clinical signs, or by its distribution—anterior or posterior uveitis, predominantly affecting the anterior or posterior segments of the eye, or panuveitis, in which both segments are affected equally. The common types are acute nongranulomatous anterior uveitis, granulomatous anterior uveitis, and posterior uveitis.

In most cases, the pathogenesis of uveitis is primarily immunologic, but infection may be the cause, particularly in immunodeficiency states. The systemic disorders associated with acute nongranulomatous anterior uveitis are the HLA-B27-related conditions ankylosing spondylitis, reactive arthritis, psoriasis, ulcerative colitis, and Crohn disease. Behçet syndrome produces both anterior uveitis, with recurrent hypopyon but little discomfort, and posterior uveitis, characteristically with branch retinal vein occlusions. Both herpes simplex and herpes zoster infections may cause nongranulomatous anterior uveitis as well as retinitis (acute retinal necrosis), which has a very poor prognosis.

Diseases producing granulomatous anterior uveitis also tend to be causes of posterior uveitis. These include sarcoidosis, toxoplasmosis, tuberculosis, syphilis, Vogt-Koyanagi-Harada syndrome (bilateral uveitis associated with alopecia, poliosis [depigmented eyelashes, eyebrows, or hair], vitiligo, and hearing loss), and sympathetic ophthalmia following penetrating ocular trauma. In toxoplasmosis, there may be evidence of previous episodes of retinochoroiditis. Syphilis characteristically produces a "salt and pepper" fundus but may present with a wide variety of clinical manifestations. The other principal pathogens responsible for ocular inflammation in HIV infection (see below) are cytomegalovirus (CMV), herpes simplex and herpes zoster viruses, mycobacteria, *Cryptococcus*, *Toxoplasma*, and *Candida*.

Autoimmune retinal vasculitis and pars planitis (intermediate uveitis) are idiopathic conditions that produce posterior uveitis.

Retinal detachment, intraocular tumors, and central nervous system lymphoma may all masquerade as uveitis.

Clinical Findings

Anterior uveitis is characterized by inflammatory cells and flare within the aqueous. In severe cases, there may be hypopyon (layered collection of white cells) (eFigure 7–6: photograph); (see photograph) and fibrin within the anterior chamber. Cells may also be seen on the corneal endothelium as keratic precipitates (KPs). In granulomatous uveitis, these are large "mutton-fat" KPs, and iris nodules may be seen. In nongranulomatous uveitis, the KPs are smaller and iris nodules are not seen. The pupil is usually small, and with the development of posterior synechiae (adhesions between the iris and anterior lens capsule), it also becomes irregular.

eFigure 7–6.

Hypopyon. (Used with permission of Ed Lee.)

Fig.

Small hypopyon.

Nongranulomatous anterior uveitis tends to present acutely with unilateral pain, redness, photophobia, and visual loss. Granulomatous anterior uveitis is more indolent, causing blurred vision in a mildly inflamed eye.

In **posterior uveitis,** there are cells in the vitreous. Inflammatory lesions may be present in the retina or choroid. Fresh lesions are yellow, with indistinct margins, and there may be retinal hemorrhages, whereas older lesions have more definite margins and are commonly pigmented. Retinal vessel sheathing may occur adjacent to such lesions or more diffusely. In severe cases, vitreous opacity precludes visualization of retinal details.

Posterior uveitis tends to present with gradual visual loss in a relatively quiet eye. Bilateral involvement is common. Visual loss may be due to vitreous haze and opacities, inflammatory lesions involving the macula, macular edema, retinal vein occlusion or, rarely, associated optic neuropathy.

Treatment

Anterior uveitis usually responds to topical corticosteroids. Occasionally, periocular corticosteroid injections or even systemic corticosteroids may be required. Dilation of the pupil is important to relieve discomfort and prevent posterior synechiae. Posterior uveitis more commonly requires systemic or intravitreal corticosteroid therapy and occasionally systemic immunosuppression with agents such as azathioprine, tacrolimus, cyclosporine, or mycophenolate. Pupillary dilation is not usually necessary. Biologic therapies are being investigated for recalcitrant anterior or posterior uveitis.

If an infectious cause is identified, specific antimicrobial therapy may be indicated. In general, the prognosis for anterior uveitis, particularly the nongranulomatous type, is better than that for posterior uveitis.

When to Refer

Any patient with suspected acute uveitis should be referred urgently to an ophthalmologist or emergently if visual loss or pain is severe.

Any patient with suspected chronic uveitis should be referred to an ophthalmologist urgently if there is more than mild visual loss.

When to Admit

Patients with severe uveitis, particularly those requiring intravenous therapy, may require hospital admission.

Cataract

Essentials of Diagnosis

- Gradually progressive blurred vision.
- No pain or redness.
- Lens opacities (may be grossly visible).

General Considerations

Cataract is a lens opacity (see photograph). It is the leading cause of blindness worldwide, but access to treatment is still limited in many areas. Cataracts are usually bilateral. They may be congenital (owing to intrauterine infections such as rubella and CMV, or inborn errors of metabolism such as galactosemia); traumatic; or secondary to systemic disease (diabetes, myotonic dystrophy, atopic dermatitis), systemic or inhaled corticosteroid treatment, or uveitis. Senile cataract is by far the most common type (see funduscopy); most persons over age 60 have some degree of lens opacity. Cigarette smoking increases the risk of cataract formation.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Fig.

Dense cataract viewed through dilated pupil with slit-lamp beam.

Fig.

Age-related cataract. **A** and **B:** "Coronary" type cortical cataract (frontal and cross-sectional views): club-shaped peripheral opacities with clear central lens; slowly progressive. **C:** "Cuneiform" type cortical cataract: peripheral spicules and central clear lens; slowly progressive. **D:** Nuclear sclerotic cataract: diffuse opacity principally affecting nucleus; slowly progressive. **E:** Posterior subcapsular cataract: plaque of granular opacity on posterior capsule; may be rapidly progressive. **F:** "Morgagnian" type (hypermature lens): the entire lens is opaque, and the lens nucleus has fallen inferiorly. (Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology*, 17th ed. McGraw-Hill, 2008.)

Clinical Findings

Even in its early stages, a cataract can be seen through a dilated pupil with an ophthalmoscope or slit lamp. As the cataract matures, the retina will become increasingly more difficult to visualize, until finally the fundus reflection is absent and the pupil is white.

Treatment

See Related Guideline from *CURRENT Practice*

In adults, functional visual impairment is the prime criterion for surgery. The cataract is usually removed by one of the techniques in which the posterior lens capsule remains (extracapsular), thus providing support for a prosthetic intraocular lens that dispenses with the need for heavy cataract glasses or contact lenses. Laser treatment may be required subsequently if the posterior capsule opacifies. Ultrasonic fragmentation (phacoemulsification) of the lens nucleus and foldable intraocular lenses allow cataract surgery to be performed through a small incision without the need for sutures, thus reducing the postoperative complication rate and accelerating visual rehabilitation. Multifocal and accommodative intraocular lenses reduce the need for both distance and reading glasses.

Management of congenital cataract is complicated by additional technical difficulties during surgery, changes in the optics of the eye with growth influencing choice of intraocular lens power, and treatment of associated amblyopia.

Prognosis

Cataract surgery in adults improves visual acuity in 95% of cases and can have a profound impact on quality of life, although expectations must be realistic. In the other

5%, there is preexisting retinal damage or operative or postoperative complications.

When to Refer

Patients with cataract should be referred to an ophthalmologist when their visual impairment adversely affects their everyday activities.

Retinal Detachment

Essentials of Diagnosis

- Curtain spreading across field of vision or sudden onset of visual loss in one eye.
- No pain or redness.
- Detachment seen by ophthalmoscopy.

General Considerations

Most cases of retinal detachment are due to development of a retinal tear (rhegmatogenous retinal detachment). This is usually spontaneous, is related to changes in the vitreous, and generally occurs in persons over 50 years of age. Myopia and cataract extraction are the two most common predisposing causes. Retinal tear may also be caused by penetrating or blunt ocular trauma. Once there is a tear in the retina, fluid vitreous is able to pass through the tear and lodge behind the sensory retina. This, combined with vitreous traction and the pull of gravity, results in progressive detachment. The superior temporal area is the most common site of detachment. The area involved rapidly increases, causing corresponding visual loss usually spreading upward across the field of vision. Central vision remains intact until the macula becomes detached.

Tractional retinal detachment occurs when there is preretinal fibrosis, such as in association with proliferative retinopathy secondary to diabetic retinopathy or retinal vein occlusion. Serous retinal detachment results from accumulation of subretinal fluid, such as in neovascular age-related macular degeneration or secondary to choroidal tumors.

Clinical Findings

On ophthalmoscopic examination in rhegmatogenous retinal detachment, the retina is seen hanging in the vitreous like a gray cloud. One or more retinal tears will usually be found on further examination. In traction retinal detachment, there is irregular retinal elevation with fibrosis. With serous retinal detachment, the retina is dome-shaped and the subretinal fluid may shift position with changes in posture.

Treatment

Treatment of rhegmatogenous retinal detachments is directed at closing the retinal tears. A permanent adhesion between the neurosensory retina, the retinal pigment epithelium, and the choroid is produced in the region of the tears by applying cryotherapy to the sclera or laser photocoagulation to the retina. To achieve apposition of the neurosensory retina to the retinal pigment epithelium while this adhesion is developing, indentation of the sclera with a silicone sponge or buckle; subretinal fluid drainage via an incision in the sclera; and injection of an expansile gas into the vitreous cavity, possibly following intraocular surgery to remove the vitreous (pars plana vitrectomy), may be required. Certain types of uncomplicated retinal detachment may be treated by pneumatic retinopexy, in which an expansile gas is initially injected into the vitreous cavity followed by positioning of the patient's head to facilitate reattachment of the retina. Once the retina is repositioned, the tear is sealed by laser photocoagulation or cryotherapy; these two methods are also used to seal retinal tears without associated detachment.

In complicated retinal detachments—particularly those in which fibroproliferative tissue has developed on the surface of the retina or within the vitreous cavity, ie, traction retinal detachments—retinal reattachment can be accomplished only by pars plana vitrectomy, direct manipulation of the retina, and internal tamponade of the retina with air, expansile gases, or even silicone oil. (The presence of an expansile gas within the eye is a contraindication to air travel, mountaineering at high altitude, and nitrous oxide anesthesia. Such gases persist in the globe for weeks after surgery.) (See Chapter 37: Disorders Due to Physical Agents.) Treatment of serous retinal detachments is determined by the underlying cause.

Prognosis

About 80% of uncomplicated rhegmatogenous retinal detachments can be cured with one operation; an additional 15% will need repeated operations; and the remainder never reattach. The visual prognosis is worse if the macula is detached or if the detachment is of long duration. Without treatment, retinal detachment often becomes total within 6 months. Spontaneous detachments are ultimately bilateral in up to 25% of cases.

When to Refer

All cases of retinal detachment must be referred urgently to an ophthalmologist, emergently if central vision is good. During transportation, the patient's head is positioned so that the detached portion of the retina will fall back with the aid of gravity.

Vitreous Hemorrhage

Patients with vitreous hemorrhage complain of sudden visual loss, abrupt onset of floaters that may progressively increase in severity or, occasionally, "bleeding within the eye". Visual acuity ranges from 20/20 to light perception only. The eye is not inflamed, and the clue to diagnosis is the inability to see fundal details clearly despite the presence of a clear lens. Causes of vitreous hemorrhage include diabetic retinopathy, retinal tears (with or without detachment), retinal vein occlusions, neovascular age-related macular degeneration, blood dyscrasias, trauma, and subarachnoid hemorrhage. In all cases, examination by an ophthalmologist is essential. Retinal tears and detachments necessitate urgent treatment (see above).

When to Refer

All patients with suspected vitreous hemorrhage must be referred urgently to an ophthalmologist.

Goff MJ et al. Causes and treatment of vitreous hemorrhage. Compr Ophthalmol Update. 2006 May-Jun;7(3):97–111. [PMID: 16882398]

Age-Related Macular Degeneration

Essentials of Diagnosis

- Older age group.
- Acute or chronic deterioration of central vision in one or both eyes.
- Distortion or abnormal size of images.

- No pain or redness.
- Macular abnormalities seen by ophthalmoscopy.

General Considerations

Age-related macular degeneration is the leading cause of permanent visual loss in the older population. The exact cause is unknown, but the prevalence increases with each decade over age 50 years (to almost 30% by age 75), and there is an association with genetically determined variations in the complement pathway. Other associated factors are race (usually white), sex (slight female predominance), family history, and a history of cigarette smoking.

Age-related macular degeneration is classified into atrophic ("dry," "geographic") and neovascular ("wet," "exudative"). Although both are progressive and usually bilateral, they differ in manifestations, prognosis, and management.

Clinical Findings

The precursor to age-related macular degeneration is age-related maculopathy, characterized by retinal drusen (see funduscopy); (eFigure 7–7: funduscopy). Hard drusen appear ophthalmoscopically as discrete yellow deposits. Soft drusen are larger, paler, and less distinct. Large, confluent soft drusen are particularly associated with neovascular age-related macular degeneration.

Fig.
Age-related macular degeneration with discrete *(small arrow)* and large confluent *(large arrow)* macular drusen. (Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology*, 17th ed. McGraw-Hill, 2008.)

eFigure 7–7.
Retinal drusen.

Atrophic degeneration is characterized by gradually progressive bilateral visual loss of moderate severity due to atrophy and degeneration of the outer retina and retinal pigment epithelium (eFigure 7–8: funduscopy). In **neovascular degeneration,** choroidal new vessels grow between the retinal pigment epithelium and Bruch's membrane, leading to accumulation of serous fluid, hemorrhage, and fibrosis (eFigure 7–9: funduscopy). The onset of visual loss is more rapid and more severe in neovascular degeneration than in atrophic degeneration.

The two eyes are frequently affected sequentially over a period of a few years. Neovascular disease accounts for about 90% of all cases of legal blindness due to age-related macular degeneration. Macular degeneration results in loss of central vision only. Peripheral fields and hence navigational vision are maintained, though these may become impaired by cataract formation for which surgery may be helpful.

eFigure 7–8.

Atrophic age-related macular degeneration.

eFigure 7–9.

Neovascular age-related macular degeneration.

Treatment

Treatment with oral vitamins and antioxidants reduces the risk of disease progression in patients with moderate age-related maculopathy or severe disease in one eye. Inhibitors of vascular endothelial growth factors (VEGF), including ranibizumab, pegaptanib, and bevacizumab, which reverse the choroidal neovascularization, result in stabilization and less frequently improvement in vision in neovascular degeneration. They have to be administered by intravitreal injection every 4–6 weeks. However, treatment is well tolerated with minimal adverse effects, although there is a small risk of intraocular infection and inflammation, retinal detachment, or traumatic cataract. Photodynamic laser therapy (PDT), involving intravenous injection of verteporfin activated by subsequent retinal laser irradiation to produce selective vascular damage, possibly supplemented by intravitreal or periocular triamcinolone, is beneficial for well-defined ("classic") and predominantly classic, as well as some small poorly-defined ("occult") choroidal neovascular membranes. Treatment may need to be repeated every 3 months. PDT may allow reduced frequency of intravitreal injections of VEGF inhibitors. Conventional laser retinal photocoagulation is only suitable for well-defined ("classic") choroidal neovascular membranes away from the fovea (extrafoveal), but these are uncommon.

Various surgical techniques to excise subfoveal neovascular membranes—or to reposition the macula away from them—have produced limited benefit.

There is no specific treatment for atrophic degeneration, but—as with the neovascular form—patients may benefit from low vision aids.

When to Refer

Older patients developing sudden visual loss due to macular disease—particularly paracentral distortion or scotoma with preservation of central acuity—should be referred urgently to an ophthalmologist.

Central & Branch Retinal Vein Occlusions

Essentials of Diagnosis

- Sudden monocular loss of vision.
- No pain or redness.

- Widespread or sectoral retinal hemorrhages seen by ophthalmoscopy.

General Considerations

All patients with retinal vein occlusion should be screened for diabetes, systemic hypertension, hyperlipidemia, and glaucoma. In younger patients, antiphospholipid antibodies, inherited thrombophilia, and hyperhomocysteinemia should be considered. Rarely, hyperviscosity syndromes, including myeloproliferative disorders, are associated with retinal vein occlusions and particularly should be considered in bilateral disease.

Clinical Findings

Symptoms and Signs

The visual impairment in central retinal vein occlusion is commonly first noticed upon waking. Ophthalmoscopic signs include widespread retinal hemorrhages, retinal venous dilation and tortuosity, retinal cotton-wool spots, and optic disk swelling (eFigure 7–10: funduscopy).

eFigure 7–10.

Central retinal vein occlusion.

Branch retinal vein occlusions may present in a variety of ways. Sudden loss of vision may occur at the time of occlusion if the fovea is involved or some time afterward from vitreous hemorrhage due to retinal new vessels. More gradual visual loss may occur with development of macular edema. In acute branch retinal vein occlusion, the retinal abnormalities (hemorrhages, venous dilation and tortuosity, and cotton-wool spots) are confined to the area drained by the obstructed vein (eFigure 7–11: funduscopy).

eFigure 7–11.

Branch retinal vein occlusion.

Laboratory Findings

Obtain screening studies for diabetes and hyperlipidemia. In younger patients, consider obtaining antiphospholipid antibodies, platelet counts to check for thrombophilia, and plasma homocysteine levels. Very high paraproteins, found on serum protein electrophoresis (particularly IgM), can cause hyperviscosity.

Complications

If central retinal vein occlusion is associated with widespread retinal ischemia, manifesting as poor visual acuity (20/200 or worse), florid retinal abnormalities, and extensive areas of capillary closure on fluorescein angiography, there is a high risk of development of neovascular (rubeotic) glaucoma, typically within first 3 months.

Branch retinal vein occlusion may be complicated by peripheral retinal neovascularization or chronic macular edema.

Treatment

Eyes at risk of neovascular glaucoma following ischemic central retinal vein occlusion can be treated by panretinal laser photocoagulation either prophylactically or as soon as there is evidence of neovascularization, the latter approach necessitating frequent monitoring. Regression of iris neovascularization has been achieved with intravitreal injections of bevacizumab, an inhibitor of VEGF. In branch retinal vein occlusion complicated by retinal neovascularization, the ischemic retina should be laser photocoagulated.

Chronic macular edema responds to laser photocoagulation in branch but not central retinal vein occlusion. Intravitreal triamcinolone or inhibitors of VEGF, such as bevacizumab, may improve chronic macular edema in both branch and nonischemic central retinal vein occlusion.

Improvement in vision has been reported after vitrectomy with direct injection of tissue plasminogen activator into the retinal venous system or incision of the sclera at the edge of the optic disk (radial optic neurotomy). Improvement has also been reported after isovolemic hemodilution in central retinal vein occlusion and after vitrectomy alone or combined with surgical incision of the retinal vascular adventitia (arteriovenous sheathotomy) and injection of tissue plasminogen activator in branch retinal vein occlusion. However, the overall value of each technique remains uncertain.

Prognosis

In central retinal vein occlusion, severity of visual loss initially is a good guide to visual outcome. Good initial visual acuity (20/60 or better) indicates a good prognosis. Visual prognosis is poor for eyes with neovascular glaucoma.

Visual outcome in branch retinal vein occlusion is determined by the severity of macular damage from hemorrhage, ischemia, or edema.

When to Refer

All patients with retinal vein occlusion should be referred urgently to an ophthalmologist.

Central & Branch Retinal Artery Occlusions

Essentials of Diagnosis

- Sudden monocular loss of vision.
- No pain or redness.
- Widespread or sectoral retinal pallid swelling seen by

ophthalmoscopy.

General Considerations

In patients 55 years of age or older with central retinal artery occlusion, giant cell arteritis must be considered. Carotid and cardiac sources of emboli must be sought in central and in branch retinal artery occlusion in particular, even if no retinal emboli are identified, so that appropriate treatment can be given to reduce the risk of stroke (see Chapter 12: Blood Vessel & Lymphatic Disorders). Migraine, oral contraceptives, systemic vasculitis, congenital or acquired thrombophilia, and hyperhomocysteinemia should be considered in young patients. Internal carotid artery dissection should be considered when there is neck pain or a recent history of neck trauma. Diabetes, hyperlipidemia, and systemic hypertension should be considered in all patients.

Clinical Findings

Symptoms and Signs

Central retinal artery occlusion presents as sudden profound monocular visual loss. Visual acuity is usually reduced to counting fingers or worse, and visual field is restricted to an island of vision in the temporal field. Ophthalmoscopy reveals pallid swelling of the retina, most obvious in the posterior segment, with a cherry-red spot at the fovea (eFigure 7–12: funduscopy). The retinal arteries are attenuated, and "box-car" segmentation of blood in the veins may be seen. Occasionally, emboli are seen in the central retinal artery or its branches. The retinal swelling subsides over a period of 4–6 weeks, leaving a relatively normal retinal appearance but a pale optic disk and attenuated arterioles.

eFigure 7–12.

Central retinal artery occlusion. (Courtesy of Esther Posner. Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology*, 17th ed. McGraw-Hill, 2008.)

Branch retinal artery occlusion may also present with sudden loss of vision if the fovea is involved, but more commonly sudden loss of visual field is the presenting complaint. Fundal signs of retinal swelling and adjacent cotton-wool spots are limited to the area of retina supplied by the occluded artery.

Clinical features of giant cell arteritis, which generally occurs in patients 55 years or older, include jaw claudication (in particular) but also may include headache, scalp tenderness, general malaise, weight loss, symptoms of polymyalgia rheumatica, and tenderness, thickening, or absence of pulse of the superficial temporal arteries. Table 20–14 lists the clinical manifestations of vasculitis.

Laboratory Findings

Screen for diabetes and hyperlipidemia in all patients. Erythrocyte sedimentation rate and C-reactive protein are usually markedly elevated in giant cell arteritis but one or both may be normal. Consider screening for other types of vasculitis (see Table 20–13). In younger patients, consider obtaining a platelet count to check for congenital or acquired thrombophilia and a plasma homocysteine level.

Imaging

Obtain duplex ultrasonography of the carotid arteries and echocardiography to seek out carotid and cardiac sources of emboli as well as internal carotid artery dissection.

Treatment

If the patient is seen within a few hours after onset, emergency treatment—including laying the patient flat, ocular massage, high concentrations of inhaled oxygen, intravenous acetazolamide, and anterior chamber paracentesis—may influence the visual outcome. Studies of early thrombolysis, particularly by local intra-arterial injection but also intravenously, have shown good results in central retinal artery occlusion not due to giant cell arteritis.

In giant cell arteritis, there is risk—highest in the first few days—of involvement of the other eye. When the diagnosis is suspected, high-dose corticosteroids (oral prednisolone 1–1.5 mg/kg/d, if necessary preceded by intravenous hydrocortisone 250–500 mg stat, or methylprednisolone 0.5–1 g/d for 1–3 days followed by oral prednisolone, especially in patients with bilateral visual loss) must be instituted immediately, possibly together with low-dose aspirin. The patient must be monitored closely to ensure that treatment is adequate. A temporal artery biopsy should be performed promptly, and if necessary, assistance should be sought from a rheumatologist.

When to Refer

- Patients with central retinal artery occlusion should be referred emergently to an ophthalmologist.
- Patients with branch retinal artery occlusion should be referred urgently.

When to Admit

- Patients with visual loss due to giant cell arteritis may require emergency admission for high-dose corticosteroid therapy and close monitoring to ensure that treatment is adequate.

Transient Monocular Blindness

Essentials of Diagnosis

- Monocular loss of vision lasting a few minutes with complete recovery.
- No retinal abnormality on ophthalmoscopy.

Transient monocular blindness results from temporary reduction in ocular perfusion. It is usually caused by retinal emboli from ipsilateral carotid disease, in which case the visual loss is characteristically described as a curtain passing vertically across the visual field with complete monocular visual loss lasting a few minutes and a similar curtain effect as the episode passes (amaurosis fugax; also called "fleeting blindness"). Other causes include cardiac emboli and severe occlusive carotid disease; giant cell arteritis and antiphospholipid syndrome may cause episodes that characteristically occur on exposure to bright light. More transient episodes occur in patients with raised intracranial pressure; these episodes last only a few seconds to 1 minute, affect one or both eyes, and are due to optic nerve head ischemia. In young patients, there is a benign entity that has been ascribed to choroidal or retinal vascular spasm.

Diagnostic Studies

The most reliable method of evaluating carotid stenosis is intra-arterial angiography. The noninvasive techniques of duplex ultrasonography, CT angiography, and magnetic resonance angiography are suitable screening methods. Electrocardiography should be performed in all cases, particularly to identify atrial fibrillation. Echocardiography, with transesophageal studies (if necessary), should be performed in young patients and in any patient with clinical evidence of a potential cardiac source of emboli.

Treatment

To reduce the risk of stroke, all patients with transient monocular blindness due to retinal emboli from ipsilateral carotid disease should be treated with low-dose aspirin or another antiplatelet drug, and their vascular risk factors should be controlled. Those patients with high-grade stenosis (70–99%), and possibly those with medium-grade (30–69%) stenosis, should be considered for carotid endarterectomy or possibly angioplasty with stenting, but surgery is less likely to be necessary than in patients with cerebral hemispheric events (see Chapter 12: Blood Vessel & Lymphatic Disorders).

In younger patients with the benign variant of transient monocular blindness, calcium channel blockers, such as slow-release nifedipine, 60 mg/d, may be effective.

When to Refer

In all cases of episodic visual loss, early ophthalmologic consultation is advisable.

Diabetic Retinopathy

Essentials of Diagnosis

- Present in about 40% of diagnosed diabetic patients.
- Present in up to 20% of type 2 diabetic patients at diagnosis.
- Mild retinal abnormalities without visual loss in background retinopathy.
- Macular edema, exudates, or ischemia in maculopathy.
- Retinal new vessels in proliferative retinopathy.

General Considerations

In the United States, diabetic retinopathy is present in about 40% of diagnosed diabetic patients. It is the leading cause of new blindness among adults aged 20–65 years; the number of affected individuals aged 65 years or older is particularly increasing. Retinopathy increases in prevalence and severity with increasing duration and poorer control of diabetes. In type 1 diabetes, retinopathy is not detectable for at least 3 years after diagnosis. In type 2 diabetes, retinopathy is present in up to 20% of patients at diagnosis and may be the presenting feature. It is broadly classified as **nonproliferative**, comprising

background retinopathy and **maculopathy**, **or proliferative**. Maculopathy and proliferative retinopathy may coexist, particularly in severe disease.

Clinical Findings

Nonproliferative retinopathy manifests as dilation of veins, microaneurysms, retinal hemorrhages, retinal edema, and hard exudates (eFigure 7–13: funduscopy). In **background retinopathy,** the abnormalities are mild and do not cause any impairment of visual acuity. Pre-proliferative retinopathy is characterized by marked vascular abnormalities and retinal hemorrhages.

Maculopathy manifests as edema, exudates, or ischemia involving the macula (Plate 52); (see funduscopy); (see funduscopy). Assessment requires stereoscopic examination of the retina, retinal imaging with optical coherence tomography (OCT), and sometimes fluorescein angiography. Visual acuity is a poor guide to the presence of treatable maculopathy—hence the need for regular ophthalmologic follow-up. Maculopathy is the most common cause of legal blindness in type 2 diabetes.

Proliferative retinopathy is characterized by neovascularization, arising from either the optic disk (see funduscopy) or the major vascular arcades. Vitreous hemorrhage is a common sequela (see funduscopy); (see funduscopy); (see funduscopy). Proliferation into the vitreous of blood vessels, with their associated fibrous component, may lead to tractional retinal detachment. Without treatment, the visual prognosis with proliferative retinopathy is generally much worse than that with nonproliferative retinopathy.

Screening

Adult and adolescent patients with diabetes should undergo at least yearly screening, by fundal photography, preferably after pupil dilation (mydriasis), or by slit-lamp examination after pupil dilation. (Failure to identify diabetic retinopathy by direct ophthalmoscopy is common, particularly if the pupils are not dilated. Non-mydriatic fundal photography, possibly with centralized screening by telemedicine, may increase rates of participation.) More frequent monitoring is required in women during pregnancy, and who plan to become pregnant.

Treatment

Treatment includes optimizing blood glucose, blood pressure, renal function, and serum lipids, although such measures are probably more important in preventing the development of retinopathy than in influencing its subsequent course.

Macular edema and exudates, but not ischemia, may respond to laser photocoagulation, intravitreal injection of corticosteroid or a VEGF inhibitor, or vitrectomy.

Proliferative retinopathy is usually treated by panretinal laser photocoagulation, preferably before vitreous hemorrhage or tractional detachment has occurred. Regression of neovascularization can also be achieved by intravitreal injection of a VEGF inhibitor. Determining whether panretinal laser photocoagulation should be undertaken for pre-proliferative retinopathy may be helped by assessing the degree of retinal ischemia on fluorescein angiography. Vitrectomy is necessary for removal of persistent vitreous hemorrhage, to improve vision and allow panretinal laser photocoagulation for the underlying retinal neovascularization, for treatment of tractional retinal detachment involving the macula, and for management of rapidly progressive proliferative disease.

Proliferative diabetic retinopathy, especially after successful laser treatment, is not a contraindication to treatment with thrombolytic agents, aspirin, or warfarin unless there has been recent vitreous or pre-retinal hemorrhage.

When to Refer

- All diabetic patients with sudden loss of vision or retinal detachment should be referred emergently to an ophthalmologist.
- Proliferative retinopathy or maculopathy requires urgent referral to an ophthalmologist.
- Pre-proliferative retinopathy or unexplained reduction of visual acuity requires early referral to an ophthalmologist.

Hypertensive Retinochoroidopathy

Systemic hypertension affects both the retinal and choroidal circulations. The clinical manifestations vary according to the degree and rapidity of rise in blood pressure and the underlying state of the ocular circulation. The most florid disease occurs in young patients with abrupt elevations of blood pressure, such as may occur in pheochromocytoma, malignant hypertension, or preeclampsia-eclampsia.

Chronic hypertension accelerates the development of atherosclerosis. The retinal arterioles become more tortuous and narrow and develop abnormal light reflexes ("silver-wiring" and "copper-wiring"). There is increased venous compression at the retinal arteriovenous crossings ("arteriovenous nicking"), an important factor predisposing to branch retinal vein occlusions. Flame-shaped hemorrhages occur in the nerve fiber layer of the retina.

Acute elevations of blood pressure result in loss of autoregulation in the retinal circulation, leading to the breakdown of endothelial integrity and occlusion of precapillary arterioles and capillaries. These pathologic changes are manifested as cotton-wool spots, retinal hemorrhages, retinal edema, and retinal exudates, often in a stellate appearance at the macula (see funduscopy). In the choroid, vasoconstriction and ischemia result in serous retinal detachments and retinal pigment epithelial infarcts. These infarcts later develop into pigmented lesions that may be focal, linear, or wedge-shaped. The abnormalities in the choroidal circulation may also affect the optic nerve head, producing ischemic optic neuropathy with optic disk swelling. Malignant hypertensive retinopathy was the term previously used to describe the constellation of clinical signs resulting from the combination of abnormalities in the retinal, choroidal, and optic disk circulation. When there is such severe disease, there is likely to be permanent retinal, choroidal, or optic nerve damage. Precipitous reduction of blood pressure may exacerbate such damage.

Blood Dyscrasias

In conditions characterized by thrombocytopenia or severe anemia, various types of hemorrhages occur in both the retina and choroid and may lead to visual loss. If macular hemorrhages have not occurred, it is possible to regain normal vision with treatment.

Sickle cell retinopathy is particularly common in hemoglobin SC disease but may also occur with other hemoglobin S variants. Manifestations include "salmon-patch" preretinal/intraretinal hemorrhages, "black sunbursts" resulting from intraretinal hemorrhage, and new vessels. Severe visual loss is rare. Retinal laser photocoagulation reduces the frequency of vitreous hemorrhage from new vessels. Surgery is occasionally needed for persistent vitreous hemorrhage or tractional retinal detachment.

AIDS

Cotton-wool spots, retinal hemorrhages, and microaneurysms are the most common ophthalmic abnormalities in AIDS patients (see funduscopy).

Fig.
Multiple retinal cotton wool spots in HIV infection. (Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology*, 17th ed. McGraw-Hill, 2008.)

CMV retinitis occurs when CD4 counts are below 50/mcL. It is characterized by progressively enlarging yellowish-white patches of retinal opacification, which are accompanied by retinal hemorrhages; they usually begin adjacent to the major retinal vascular arcades (Plate 53). Patients are often asymptomatic until there is involvement of the fovea or optic nerve or until retinal detachment develops.

Plate 53.

Retinal changes in HIV infection: cytomegalovirus retinitis. (Courtesy of Elizabeth Graham; Reproduced, with permission, from Riordan-Eva P and Witcher, JP. *Vaughn & Asbury's General Ophthalmology*, 17th edition. McGraw-Hill, 2008.)

Choices for initial therapy are (1) intravenous—ganciclovir 5 mg/kg twice a day, foscarnet 60 mg/kg three times a day, or cidofovir 5 mg/kg once weekly, usually for 2 weeks; (2) oral—valganciclovir 900 mg twice daily; or (3) local administration, using either intravitreal injection of ganciclovir, foscarnet, or fomivirsen or the sustained-release ganciclovir intravitreal implant. Intravitreal cidofovir is effective, but there is a high incidence of uveitis, low intraocular pressure, and ciliary body necrosis. Other major side effects are neutropenia and thrombocytopenia with systemic ganciclovir and nephrotoxicity with foscarnet and cidofovir. Doses of both ganciclovir and foscarnet are adjusted in patients with renal failure. Oral probenecid and intravenous hydration are used to minimize nephrotoxicity from cidofovir. All available agents are virostatic. Maintenance therapy can be conducted with lower-dose intravenous therapy (ganciclovir 3.75 mg/kg/d or foscarnet 60 mg/kg/d for 5 days each week, or cidofovir 5 mg/kg once every 2 weeks), with oral ganciclovir (3 g/d) or oral valganciclovir 900 mg once daily, or with intravitreal therapy. Local therapy tends to be more effective than systemic therapy and avoids systemic side effects, but there is a risk of intraocular complications, and the incidence of retinitis in the fellow eye and of extraocular CMV infection is higher. Unresponsive disease or reactivation during maintenance therapy can be managed by changing to a different agent or by use of combination therapy. Retinal detachment, either due to retinitis or as a complication of intravitreal therapy, requires vitrectomy and intravitreal silicone oil. Oral ganciclovir as prophylaxis against CMV retinitis in patients with low CD4 counts or high CMV burdens has not been found to be worthwhile.

Antiretroviral therapy may result in reduction of HIV virus load and increase in CD4 counts, and even regression of CMV retinitis without the use of anti-CMV therapy. If the CD4 count is maintained above 100/mcL, it may be possible to discontinue maintenance anti-CMV therapy. In patients with regressed CMV retinitis and restored CD4 counts, highly active antiretroviral therapy (HAART) commonly leads to "immune recovery" uveitis, which may lead to visual loss from cataract or retinal complications.

Other ophthalmic manifestations of opportunistic infections occurring in AIDS patients include herpes simplex retinitis, toxoplasmic and candidal chorioretinitis, herpes zoster ophthalmicus, and various entities due to syphilis or tuberculosis. Kaposi sarcoma of the conjunctiva and orbital lymphoma may also be seen on rare occasions (see Chapter 31: HIV Infection & AIDS).

Ischemic Optic Neuropathy

Essentials of Diagnosis

- Sudden painless visual loss with signs of optic nerve dysfunction.
- Optic disk swelling in anterior ischemic optic neuropathy.

Anterior ischemic optic neuropathy—due to inadequate perfusion of the posterior ciliary arteries that supply the anterior portion of the optic nerve—produces sudden visual loss, usually with an altitudinal field defect, and optic disk swelling (eFigure 7–16: funduscopy). In older patients, it is often caused by giant cell arteritis, which necessitates emergency high-dose systemic corticosteroid treatment to prevent visual loss in the other eye. (See Central & Branch Retinal Artery Occlusions, above and Polymyalgia Rheumatica & Giant Cell Arteritis.) The predominant factor predisposing to nonarteritic anterior ischemic optic neuropathy is congenitally crowded optic disks. Other causative factors include systemic hypertension, diabetes, hyperlipidemia, systemic vasculitis, inherited or acquired thrombophilia, and possibly ingestion of sildenafil and sleep apnea.

eFigure 7–16.

Anterior ischemic optic neuropathy. (Courtesy of Paul Riordan-Eva.)

Ischemic optic neuropathy, usually involving the retrobulbar optic nerve and thus not causing any optic disk swelling (**posterior ischemic optic neuropathy**), may occur after severe blood loss or nonocular surgery, particularly prolonged lumbar spine surgery. Early correction of anemia and systemic hypotension may be beneficial.

When to Refer

Patients with ischemic optic neuropathy should be referred urgently to an ophthalmologist.

When to Admit

Patients with ischemic optic neuropathy due to giant cell arteritis may require emergency admission for high-dose corticosteroid therapy and close monitoring to ensure that treatment is adequate.

Optic Neuritis

Essentials of Diagnosis

- Subacute unilateral visual loss with signs of optic nerve dysfunction.
- Pain exacerbated by eye movements.
- Optic disk usually normal in acute stage but subsequently developing pallor.

General Considerations

Inflammatory optic neuropathy (optic neuritis) is strongly associated with demyelinating disease, particularly multiple sclerosis but also acute disseminated encephalomyelitis. It also occurs in sarcoidosis; as a component of neuromyelitis optica (Devic syndrome); with viral infections (including measles, mumps, influenza and those caused by the varicella zoster virus); with various autoimmune disorders, particularly systemic lupus erythematosus; and by spread of inflammation from meninges, orbital tissues, or paranasal sinuses.

Clinical Findings

Optic neuritis in demyelinating disease is characterized by unilateral loss of vision, which usually develops over a few days. Vision ranges from 20/30 to no perception of light. Commonly there is pain in the region of the eye, particularly on eye movements. Field loss is usually a central scotoma, but a wide range of monocular field defects is possible. There is marked loss of color vision and a relative afferent pupillary defect. In about two-thirds of cases, the optic nerve is normal during the acute stage (retrobulbar optic neuritis). In the remainder, the optic disk is swollen (papillitis) with occasional flame-shaped peripapillary hemorrhages. Visual acuity usually improves within 2–3 weeks and returns to 20/40 or better in 95% of previously unaffected eyes. Optic atrophy subsequently develops if there has been destruction of sufficient optic nerve fibers (see funduscopy). Any patient with presumed demyelinating optic neuritis in which visual recovery does not occur or there are other atypical features should undergo further investigation, including imaging studies to exclude a compressive lesion.

Fig.

Bilateral optic atrophy due to optic neuritis.

Treatment

In acute demyelinating optic neuritis, intravenous methylprednisolone therapy for 3 days followed by a tapering course of oral prednisolone accelerates visual recovery, although in clinical practice the oral taper is rarely prescribed. Use in an individual patient is determined by the degree of visual loss, the state of the fellow eye, and the patient's visual requirements.

Optic neuritis due to sarcoidosis, neuromyelitis optica, herpes zoster, or systemic lupus erythematosus generally has a poorer prognosis and requires more prolonged corticosteroid therapy.

Prognosis

Among patients with a first episode of clinically isolated optic neuritis, multiple sclerosis will develop in 50% within 15 years but the visual and neurologic prognosis is good. The major risk factors are female gender, multiple white matter lesions on brain MRI scan, and cerebrospinal fluid oligoclonal bands. In patients with multiple cerebral white matter lesions, long-term interferon therapy reduces the risk of subsequent development of multiple sclerosis by 25% at 5 years, although the effect on long-term disability remains uncertain and some patients do not respond.

When to Refer

All patients with optic neuritis should be referred urgently for ophthalmologic or neurologic assessment.

Optic Disk Swelling

Optic disk swelling may result from intraocular disease, orbital and optic nerve lesions, severe hypertensive retinochoroidopathy, or raised intracranial pressure, the last necessitating urgent imaging to exclude an intracranial mass or cerebral venous sinus occlusion.

Intraocular causes include central retinal vein occlusion, posterior uveitis, and posterior scleritis. Optic nerve lesions causing disk swelling include optic neuritis; anterior ischemic optic neuropathy; optic disk drusen; optic nerve sheath meningioma; and nerve infiltration by sarcoidosis, leukemia, or lymphoma. Any orbital lesion causing nerve compression may produce disk swelling.

Papilledema (optic disk swelling due to raised intracranial pressure) is usually bilateral and most commonly produces enlargement of the blind spot without loss of acuity (Plate 54); (see funduscopy); (see funduscopy). Chronic papilledema, as in idiopathic intracranial hypertension and dural venous sinus occlusion, or severe acute papilledema may be associated with visual field loss and occasionally with profound loss of acuity (eFigure 7–18: funduscopy); (see funduscopy). All patients with chronic papilledema must be monitored carefully—especially their visual fields—and cerebrospinal fluid shunt or optic nerve sheath fenestration should be considered in those with progressive visual failure not controlled by medical therapy (weight loss where appropriate and acetazolamide).

eFigure 7–18.

Chronic papilledema. (Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology*, 17th ed. McGraw-Hill, 2008.)

Optic disk drusen and congenitally crowded optic disks, which are associated with hyperopia, cause optic disk elevation that may be mistaken for swelling (pseudopapilledema). Exposed optic disk drusen may be obvious clinically or can be demonstrated by their autofluorescence. Buried drusen are best detected by orbital ultrasound or CT scanning. Other family members may be similarly affected.

Ocular Motor Palsies

In complete **third nerve paralysis**, there is ptosis with a divergent and slightly depressed eye (see photograph). Extraocular movements are restricted in all directions except laterally (preserved lateral rectus function). Intact fourth nerve (superior oblique) function is detected by the presence of inward rotation on attempted depression of the eye.

Fig.

Pupil-sparing third nerve palsy in diabetes mellitus. Sudden painful ophthalmoplegia, left ptosis, failure of adduction, and normal pupillary responses. (Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology,* 17th ed. McGraw-Hill, 2008.)

Pupillary involvement (dilated pupil that does not react to light shone in either eye) is an important sign differentiating "surgical," including traumatic, from "medical" causes of isolated third nerve palsy. Compressive lesions of the third nerve—eg, aneurysm of the posterior communicating artery and uncal herniation due to a supratentorial mass lesion—characteristically have pupillary involvement. Patients with painful acute isolated third nerve palsy and pupillary involvement are assumed to have a posterior communicating artery aneurysm until this has been excluded. Pituitary apoplexy is a rarer cause. Medical causes of isolated third nerve palsy include diabetes, hypertension, and giant cell arteritis.

Fourth nerve paralysis causes upward deviation of the eye with failure of depression on adduction. There is vertical and torsional diplopia that becomes most apparent on attempted reading and descending stairs. Many cases with similar clinical features are due to congenital orbital musculo-facial anomaly, although labeled as congenital fourth nerve palsy. Trauma is a major cause of acquired—particularly bilateral—fourth nerve palsy, but posterior fossa tumor and medical causes such as in third nerve palsies should also be considered.

Sixth nerve paralysis causes convergent squint in the primary position with failure of abduction of the affected eye, producing horizontal diplopia that increases on gaze to the affected side and on looking into the distance (see photograph). It is an important sign of raised intracranial pressure. Sixth nerve palsy may also be due to trauma, neoplasms, brainstem lesions, or medical causes.

Fig.

Polyarteritis nodosa. Bilateral sixth nerve palsies. (Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology*, 17th ed. McGraw-Hill, 2008.)

An intracranial or intraorbital mass lesion should be considered in any patient with an isolated ocular motor palsy. In patients with isolated ocular motor nerve palsies presumed to be due to medical causes, brain MRI is generally only necessary if recovery has not begun within 3 months, although some authors suggest that it should be undertaken in all cases.

Ocular motor nerve palsies occurring in association with other neurologic signs may be due to lesions in the brainstem, the cavernous sinus, or in the orbit. Lesions around the cavernous sinus involve the upper divisions of the trigeminal nerve, the ocular motor nerves, and occasionally the optic chiasm. Orbital apex lesions involve the optic nerve and the ocular motor nerves.

Myasthenia and dysthyroid eye disease should also be considered in the differential diagnosis of disordered extraocular movements.

When to Refer

- Any patient with recent onset isolated third nerve palsy, particularly if there is pupillary involvement or pain, must be referred emergently for neurologic assessment and possible investigation for intracranial aneurysm.
- All patients with recent onset double vision should be referred urgently to an ophthalmologist or neurologist, particularly if there is multiple cranial

nerve dysfunction or other neurologic abnormalities.

When to Admit

Patients with double vision due to giant cell arteritis may require emergency admission for high-dose corticosteroid therapy and close monitoring to ensure that treatment is adequate.

Dysthyroid Eye Disease

Dysthyroid eye disease is a syndrome of clinical and orbital imaging abnormalities caused by deposition of mucopolysaccharides and infiltration with chronic inflammatory cells of the orbital tissues, particularly the extraocular muscles. It usually occurs in association with autoimmune hyperthyroidism, when it is known as Graves disease. However clinical or laboratory evidence of thyroid dysfunction and thyroid autoantibodies may not be detectable at presentation or even on long-term follow-up. Radioiodine therapy and cigarette smoking increase its severity.

The primary clinical features are proptosis, lid retraction and lid lag, conjunctival chemosis and episcleral inflammation, and extraocular muscle dysfunction (see photograph). Resulting symptoms are cosmetic abnormalities, surface irritation, which usually responds to artificial tears, and diplopia, which should be treated conservatively (eg, with prisms) in the active stages of the disease and only by surgery when the disease has been static for at least 6 months. The important complications are corneal exposure and optic nerve compression, both of which may lead to marked visual loss. The primary imaging features are enlargement of the extraocular muscles, usually affecting both orbits (see CT scan).

Fig.

Thyroid ophthalmopathy. **Top:** Proptosis, lid edema, lid retraction, chemosis, ophthalmoplegia, and visual loss in thyroid eye disease. **Bottom:** CT scan in thyroid eye disease showing gross thickening of the extraocular muscles, particularly in relation to the orbital apex. The increased intraorbital pressure is producing convexity of the medial orbital wall. (Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology*, 17th ed. McGraw-Hill, 2008.)

Treatment

Treatment options for optic nerve compression or severe corneal exposure are intravenous pulse methylprednisolone therapy (eg, 1 g daily for 3 days, repeated weekly for 3 weeks), oral prednisolone 80–100 mg/d, radiotherapy, or surgery (usually consisting of extensive removal of bone from the medial, inferior, and lateral walls of the orbit), either singly or in combination.

The optimal management of moderately severe dysthyroid eye disease without visual loss is controversial. Systemic corticosteroids and radiotherapy have not been shown to provide definite long-term benefit. Peribulbar corticosteroid injections have been advocated. Surgical decompression may be justified in patients with marked proptosis. Lateral tarsorrhaphy may be used for moderately severe corneal exposure. Other procedures are particularly useful for correcting lid retraction but should not be undertaken until the orbital disease is quiescent and orbital decompression or extraocular muscle surgery has been undertaken. Establishing and maintaining euthyroidism are important in all cases.

When to Refer

All patients with dysthyroid eye disease should be referred to an ophthalmologist, urgently if there is reduced vision.

Orbital Cellulitis

Orbital cellulitis is characterized by fever, proptosis, restriction of extraocular movements, and swelling with redness of the lids (see photograph). Infection of the paranasal sinuses is the usual underlying cause. Immediate treatment with intravenous antibiotics is necessary to prevent optic nerve damage and spread of infection to the cavernous sinuses, meninges, and brain. The response to antibiotics is usually excellent, but abscess formation may necessitate surgical drainage. In immunocompromised patients, zygomycosis must be considered.

Ocular Trauma

Conjunctival & Corneal Foreign Bodies

If a patient complains of "something in my eye" and gives a consistent history, a foreign body is usually present on the cornea or under the upper lid even though it may not be visible (see photograph). Visual acuity should be tested before treatment is instituted, as a basis for comparison in the event of complications.

Fig.

Metallic corneal foreign body. (Courtesy of A Rosenberg. Reproduced with permission from Riordan-Eva P, Whitcher JP: *Vaughn & Asbury's General Ophthalmology*, 17th ed. McGraw-Hill, 2008.)

After a local anesthetic (eg, proparacaine, 0.5%) is instilled, the eye is examined with a hand flashlight, using oblique illumination, and loupe. Corneal foreign bodies may be made more apparent by the instillation of sterile fluorescein. They are then removed with a sterile wet cotton-tipped applicator or hypodermic needle. Polymyxin-bacitracin ophthalmic ointment should be instilled. It is not necessary to patch the eye.

Steel foreign bodies usually leave a diffuse rust ring. This requires excision of the affected tissue and is best done under local anesthesia using a slit lamp. **Caution:** Anesthetic drops should not be given to the patient for self-administration.

If there is no infection, a layer of corneal epithelial cells will line the crater within 24 hours. The intact corneal epithelium forms an effective barrier to infection, but once it is disturbed the cornea becomes extremely susceptible to infection. Early infection is manifested by a white necrotic area around the crater and a small amount of gray exudate.

In the case of a foreign body under the upper lid, a local anesthetic is instilled and the lid is everted by grasping the lashes gently and exerting pressure on the mid portion of the outer surface of the upper lid with an applicator. If a foreign body is present, it can easily be removed by passing a wet sterile cotton-tipped applicator across the conjunctival surface.

When to Refer

Urgent referral to an ophthalmologist should be arranged if a corneal foreign body cannot be removed or if there is suspicion of corneal infection.

Intraocular Foreign Body

Intraocular foreign body requires emergency treatment by an ophthalmologist. Patients giving a history of "something hitting the eye"—particularly while hammering on metal or using grinding equipment—must be assessed for this possibility, especially when no corneal foreign body is seen, a corneal or scleral wound is apparent, or there is marked visual loss or media opacity. Such patients must be treated as for corneal laceration (see below) and referred without delay. Intraocular foreign bodies significantly increase the risk of intraocular infection (see funduscopy).

Fig.

Funduscopic view of metallic foreign body on retina.

When to Refer

Patients with suspected intraocular foreign body must be referred emergently to an ophthalmologist.

Szijártó Z et al. Prognosis of penetrating eye injuries with posterior segment intraocular foreign body. Graefes Arch Clin Exp Ophthalmol. 2008 Jan;246(1):161–5. [PMID: 17674019]

Corneal Abrasions

A patient with a corneal abrasion complains of severe pain and photophobia. There is often a history of trauma to the eye, commonly involving a fingernail, piece of paper, or contact lens. Visual acuity is recorded, and the cornea and conjunctiva are examined with a light and loupe to rule out a foreign body. If an abrasion is suspected but cannot be seen, sterile fluorescein is instilled into the conjunctival sac: the area of corneal abrasion will stain a deeper green than the surrounding cornea (see photograph).

Treatment includes polymyxin-bacitracin ophthalmic ointment, mydriatic (cyclopentolate 1%), and analgesics either topical or oral nonsteroidal anti-inflammatory agents. Padding the eye is probably not helpful for small abrasions. Recurrent corneal erosion may follow corneal abrasions.

Turner A et al. Patching for corneal abrasion. Cochrane

Database Syst Rev. 2006 Apr 19;(2):CD004764. [PMID: 16625611]

Contusions

Contusion injuries of the eye and surrounding structures may cause ecchymosis ("black eye"), subconjunctival hemorrhage, edema or rupture of the cornea, hemorrhage into the anterior chamber (hyphema), rupture of the root of the iris (iridodialysis), paralysis of the pupillary sphincter, paralysis of the muscles of accommodation, cataract, dislocation of the lens, vitreous hemorrhage, retinal hemorrhage and edema (most common in the macular area), detachment of the retina, rupture of the choroid, fracture of the orbital floor ("blowout fracture"), or optic nerve injury. Many of these injuries are immediately obvious; others may not become apparent for days or weeks. The possibility of globe injury must always be considered in patients with facial injury, particularly if there is an orbital fracture. Patients with moderate to severe contusions should be seen by an ophthalmologist.

Any injury causing hyphema involves the danger of secondary hemorrhage, which may cause intractable glaucoma with permanent visual loss (Plate 55); (see photograph); (see photograph). The patient should be advised to rest until complete resolution has occurred.

Daily ophthalmologic assessment is essential. Aspirin and any drugs inhibiting coagulation increase the risk of secondary hemorrhage and are to be avoided. Sickle cell anemia or trait adversely affects outcome.

Lacerations

Lids

If the lid margin is lacerated, the patient should be referred for specialized care, since permanent notching may result. Lacerations of the lower eyelid near the inner canthus often sever the lower canaliculus. Lid lacerations not involving the margin may be sutured like any skin laceration.

Jordan DR et al. Pathogenesis of canalicular lacerations. Ophthal Plast Reconstr Surg. 2008 Sep–Oct;24(5):394–8. [PMID: 18806662]

Naik MN et al. Management of canalicular lacerations: epidemiological aspects and experience with Mini-Monoka monocanalicular stent. Am J Ophthalmol. 2008 Feb;145(2):375–80. [PMID: 18061134]

Savar A et al. Canalicular involvement in dog bite related eyelid lacerations. Ophthal Plast Reconstr Surg. 2008 Jul–Aug;24(4):296–8. [PMID: 18645435]

Conjunctiva

In lacerations of the conjunctiva, sutures are not necessary. To prevent infection, sulfonamides or other antibiotics are instilled into the eye until the laceration is healed.

Cornea or Sclera

Patients with suspected corneal or scleral lacerations must be seen promptly by an ophthalmologist [Plate 56; (see photograph)]. Manipulation is kept to a minimum, since pressure may result in extrusion of the intraocular contents. The eye is bandaged lightly and covered with a metal shield that rests on the orbital bones above and below. The patient should be instructed not to squeeze the eye shut and to remain still. The eye is routinely imaged by radiography, and CT scanning if necessary, to identify and localize any metallic intraocular foreign body. MRI is contraindicated because of the risk of movement of the foreign body in the magnetic field. Endophthalmitis occurs in over 5% of open globe injuries.

Plate 56.

Ultraviolet Keratitis (Actinic Keratitis)

Ultraviolet burns of the cornea are usually caused by use of a sunlamp without eye protection, exposure to a welding arc, or exposure to the sun when skiing ("snow blindness"). There are no immediate symptoms, but about 6–12 hours later the patient complains of agonizing pain and severe photophobia. Slit-lamp examination after instillation of sterile fluorescein shows diffuse punctate staining of both corneas.

Treatment consists of binocular patching and instillation of 1–2 drops of 1% cyclopentolate (to relieve the discomfort of ciliary spasm). All patients recover within 24–48 hours without complications. Local anesthetics should not be prescribed because they delay corneal epithelial healing.

Chemical Conjunctivitis & Keratitis

Chemical burns are treated by copious irrigation of the eyes with saline solution, plain water, or buffering solution if available as soon as possible after exposure. Neutralization of an acid with an alkali or vice versa generates heat and may cause further damage. Alkali injuries are more serious and require prolonged irrigation, since alkalies are not precipitated by the proteins of the eye as are acids. It is important to remove any retained particulate matter such as is typically present in injuries involving cement and building plaster. This may require double eversion of the upper lid. The pupil should be dilated with 1% cyclopentolate, 1 drop twice a day, to relieve discomfort and prophylactic topical antibiotics should be started. In moderate to severe injuries, intensive topical corticosteroids and topical and systemic vitamin C are also necessary. Complications include mucus deficiency, scarring of the cornea and conjunctiva, symblepharon (adhesions between the tarsal and bulbar conjunctiva), tear duct obstruction, and secondary infection. It can be difficult to assess severity of chemical burns without slit-lamp examination.

Peate WF. Work-related eye injuries and illnesses. Am Fam Physician. 2007 Apr 1;75(7):1017–22. [PMID: 17427615]

Principles of Treatment of Ocular Infections

Before determining the drug of choice for treatment of ocular infection, preferably the causative organisms is identified, but in most cases empiric treatment, guided by knowledge of local patterns of microbial resistance, is used in the first instance. In the treatment of conjunctivitis and for prophylaxis against ocular infection, it is preferable to use a drug that is not given systemically. Although fluoroquinolones, including the fourth-generation fluoroquinolones, are advocated for the treatment of conjunctivitis, they should be reserved for treatment of bacterial keratitis and other serious infections. Of the available local antibacterial agents, sodium sulfacetamide is effective and inexpensive. It is available in ointment or solution form. Combined bacitracin-polymyxin ointment is often used prophylactically after corneal foreign body removal for the protection it affords against both gram-positive and gram-negative organisms.

Among the most effective broad-spectrum antibiotics for severe ocular infections are fluoroquinolones (ciprofloxacin, ofloxacin, norfloxacin, levofloxacin, moxifloxacin, and gatifloxacin [not available in the

United States]), aminoglycosides (gentamicin and tobramycin), and cephalosporins. For pneumococcus, one of the newer fluoroquinolones, particularly levofloxacin or gatifloxacin if -lactamase resistance is present, or penicillin G is required.

A relatively limited range of proprietary ophthalmic preparations is available. Intraocular and unusual corneal infections require specially formulated preparations, made either from proprietary parenteral preparations or de novo.

Method of Administration

Most ocular anti-infective drugs are administered topically. Ointments have greater therapeutic effectiveness than solutions, since contact can be maintained longer. However, they do cause blurring of vision; if this must be avoided, solutions should be used. Subconjunctival injections are sometimes used to provide more prolonged effect from a single administration. Intravitreal injections, prepared from parenteral formulations, are used for severe intraocular infection.

Systemic administration is required for some intraocular infections, orbital cellulitis, dacryocystitis, gonococcal keratoconjunctivitis, inclusion conjunctivitis, and severe external infection that do not respond to local treatment.

Treatment of Ocular Disorders

Table 7–2 lists commonly used ophthalmic drugs and their indications and costs.

Table 7–2. Topical ophthalmic agents.			
Agent	**Cost/Size**[1]	**Recommended Regimen**	**Indications**
ANTIBACTERIAL AGENTS[2]			
Bacitracin 500 units/g ointment (various)[3]	$4.75/3.5 g	Refer to package insert (instructions vary)	Ocular surface infection involving lid, conjunctiva, or cornea.
Chloramphenicol 1% (10 mg/g) ointment (compounding pharmacy)[4]	No U.S. price		
Ciprofloxacin HCl (Ciloxan)	0.3% solution: $45.89/5 mL		
	0.3% ointment:		

	$79.38/3.5 g		
Erythromycin 0.5% ointment (various)[5]	$5.73/3.5 g		
Fusidic acid 1% in gel (Fucithalmic)	Not available in United States		
Gatifloxacin 0.3% solution (Zymar)	$74.54/5 mL		
Gentamicin sulfate 0.3% solution (various)	$9.50/5 mL		
Gentamicin sulfate 0.3% ointment (various)	$17.70/3.5 g		
Levofloxacin solution (Iquix 1.5%)	$67.20/5 mL		
Moxifloxacin sulfate 0.5%	$70.68/3 mL		

solution (Vigamox)			
Norfloxacin 0.3% solution (Chibroxin)	Not available in United States		
Ofloxacin 0.3% solution (Ocuflox)	$40.46/5 mL		
Polymyxin B/Trimethoprim sulfate 10,000 /mL/1 mg/mL	$17.42/10 mL		
Tobramycin 0.3% solution (various)	$15.00/5 mL		
Tobramycin 0.3% ointment (Tobrex)	$67.62/3.5 g		
Sulfacetamide sodium 10% solution (various)	$5.08/15 mL	1 or 2 drops every 1–3 hours	
Sulfacetamide sodium 10%	$15.25/3.5 g	Apply small amount (0.5	

ointment (various)		inch) into lower conjunctival sac once to four times daily and at bedtime	
ANTIFUNGAL AGENTS			
Natamycin 5% suspension (Natacyn)	$189.00/15 mL	1 drop every 1–2 hours	Fungal ocular infections.
ANTIVIRAL AGENTS			
Acyclovir 3% ointment (Zovirax)	Not available in United States	5 times daily	Herpes simplex virus keratitis.
Trifluridine 1% solution (Viroptic)	$95.64/7.5 mL	1 drop onto cornea every 2 hours while awake for a maximum daily dose of 9 drops until resolution occurs; then an additional	

		7 days of 1 drop every 4 hours while awake (minimum five times daily)	
ANTI-INFLAMMATORY AGENTS			
Antihistamines [7]			
Azelastine HCl 0.05% ophthalmic solution (Optivar)	$97.93/6 mL	1 drop two to four times daily (up to 6 weeks)	Allergic eye disease.
Levocabastine HCl 0.05% ophthalmic solution (Livostin)	$96.40/10 mL	1 drop four times daily (up to 2 weeks)	Allergic eye disease.
Emedastine difumarate 0.05% solution (Emadine)	$70.62/5 mL	1 drop four times daily	
Epinastine HCl 0.05% ophthalmic	$99.29/5 mL	1 drop twice daily (up to 8 weeks)	

solution (Elestat)			
Mast cell stabilizers			
Cromolyn sodium 4% solution (Crolom)	$37.20/10 mL	1 drop four to six times daily	Allergic eye disease.
Ketotifen fumarate 0.025% solution (Zaditor)	$12.19/5 mL	1 drop two to four times daily	
Lodoxamide tromethamine 0.1% solution (Alomide)	$91.20/10 mL	1 or 2 drops four times daily (up to 3 months)	
Nedocromil sodium 2% solution (Alocril)	$89.40/5 mL	1 drop twice daily	
Olopatadine hydrochloride 0.1% solution (Patanol)	$98.10/5 mL	1 drop twice daily	
Nonsteroidal anti-inflammatory agents[8]			

Bromfenac 0.09% solution (Xibrom)	$113.38/2.5 mL	1 drop to operated eye twice daily beginning 24 hours after cataract surgery and continuing through first 2 postoperative weeks	Treatment of postoperative inflammation following cataract extraction.
Diclofenac sodium 0.1% solution (Voltaren)	$55.15/5 mL	1 drop to operated eye four times daily beginning 24 hours after cataract surgery and continuing through first 2 postoperative weeks	Treatment of postoperative inflammation following cataract extraction and laser corneal surgery.
Flurbiprofen sodium 0.03% solution (various)	$8.73/2.5 mL	1 drop every half hour beginning 2 hours before	Inhibition of intraoperative miosis. Treatment of

		surgery; 1 drop to operated eye four times daily beginning 24 hours after cataract surgery	cystoid macular edema and inflammation after cataract surgery.
Ketorolac tromethamine 0.5% solution (Acular)	$100.87/5 mL	1 drop four times daily	Treatment of allergic eye disease, postoperative inflammation following cataract extraction and laser corneal surgery.
Nepafenac 0.1% suspension (Nevanac)	$92.88/3 mL	1 drop to operated eye three times daily beginning 24 hours after cataract	Treatment of postoperative inflammation following cataract extraction.

		surgery and continuing through first 2 postoperative weeks	
Corticosteroids [9]			
Dexamethasone sodium phosphate 0.1% solution (various)	$17.31/5 mL	1 or 2 drops as often as indicated by severity; use every hour during the day and every 2 hours during the night in severe inflammation; taper off as inflammation decreases	Treatment of steroid-responsive inflammatory conditions of anterior segment.
Dexamethasone sodium phosphate 0.05% ointment (various)	$6.34/3.5 g	Apply thin coating on lower conjunctival sac three or four times daily	

Fluorometholone 0.1% suspension (various)[10]	$16.01/10 mL	1 or 2 drops as often as indicated by severity; use every hour during the day and every 2 hours during the night in severe inflammation; taper off as inflammation decreases	
Fluorometholone 0.25% suspension (FML Forte)[10]	$38.63/10 mL		
Fluorometholone 0.1% ointment (FML S.O.P.)	$34.92/3.5 g	Apply thin coating on lower conjunctival sac three or four times daily	
Loteprednol	$117.04/1	1 or 2 drops	

etabopate 0.5% (Lotemax)	0 mL	four times daily	
Prednisolone acetate 0.12% suspension (Pred Mild)	$36.14/10 mL	1 or 2 drops as often as indicated by severity of inflammation; use every hour during the day and every 2 hours during the night in severe inflammation; taper off as inflammation decreases	
Prednisolone sodium phosphate 0.125% solution (compounding pharmacy)	No U.S. price		
Prednisolone acetate 1% suspension (various)	$23.10/10 mL		
Prednisolone sodium phosphate 1% solution (various)	$24.06/10 mL		
Rimexolone 1% suspension (Vexol)	$64.74/10 mL		
Immunomodulator			

Cyclosporine 0.05% emulsion (Restasis) 0.4 mL/container	$123.32/30 containers	1 drop twice daily	Dry eyes and severe allergic eye disease.
AGENTS FOR GLAUCOMA AND OCULAR HYPERTENSION			
Sympathomimetics			
Apraclonidine HCl 0.5% solution (Iopidine)	$86.22/5 mL	1 drop three times daily	Reduction of intraocular pressure. Expensive. Reserve for treatment of resistant cases.
Apraclonidine HCl 1% solution (Iopidine)	$14.33/unit dose	1 drop 1 hour before and immediately after anterior segment laser surgery	To control or prevent elevations of intraocular pressure after laser trabeculoplasty or iridotomy.
Brimonidine	$32.65/5	1 drop two or	Reduction of

tartrate 0.2% solution (Alphagan)	mL	three times daily	intraocular pressure.
Dipivefrin HCl 0.1% solution (Propine)[11]	$14.06/5 mL	1 drop every 12 hours	Open-angle glaucoma.
-Adrenergic blocking agents			
Betaxolol HCl 0.5% solution and 0.25% suspension (Betoptic S)[12]	0.5%: $46.68/10 mL 0.25%: $109.50/10 mL	1 drop twice daily	Reduction of intraocular pressure.
Carteolol HCl 1% and 2% solution (Various, Teoptic[13])	1%: $37.07/10 mL; 2%: TEOPTIC not available in the U.S.	1 drop twice daily	
Levobunolol HCl 0.25% and 0.5% solution (Betagan)[14]	0.5%: $32.25/10 mL	1 drop once or twice daily	

Metipranolol HCl 0.3% solution (OptiPranolol)[14]	$26.85/10 mL	1 drop twice daily	
Timolol 0.25% and 0.5% solution (Betimol)[14]	0.5%: $64.80/10 mL	1 drop once or twice daily	
Timolol maleate 0.25% and 0.5% solution (Timoptic) and 0.25% and 0.5% gel (Timoptic-XE)[14]	0.5% solution: $32.35/10 mL	1 drop once or twice daily	
	0.5% gel: $27.00/5 mL		
Miotics			
Pilocarpine HCl (various)[15] 1–4%, 6%, 8%, and 10%	2%: $11.80/15 mL	1 drop three or four times daily	Reduction of intraocular pressure, treatment of acute or

Pilocarpine HCl 4% gel (Pilopine HS)	$54.24/4 g	Apply 0.5-inch ribbon in lower conjunctival sac at bedtime	chronic angle-closure glaucoma, and pupillary constriction.
Carbonic anhydrase inhibitors			
Dorzolamide HCl 2% solution (Trusopt)	$71.28/10 mL	1 drop three times daily	Reduction of intraocular pressure.
Brinzolamide 1% suspension (Azopt)	$91.38/10 mL	1 drop three times daily	
Prostaglandin analogs			
Bimatoprost 0.03% solution (Lumigan)	$80.53/2.5 mL	1 drop once daily at night	Reduction of intraocular pressure.
Latanoprost 0.005% solution (Xalatan)	$77.26/2.5 mL	1 drop once or twice daily at night	
Travoprost 0.004% solution (Travatan)	$80.88/2.5 mL	1 drop once daily at night	
Unoprostone	Not	1 drop twice	FYI only:

isopropyl 0.15% solution (Rescula)	available in United States	daily	Rescula is FDA approved in the United States but is not being sold here
Combined preparations			
Xalacom (latanoprost 0.005% and timolol 0.5%)	Not available in United States	1 drop daily in the morning	Reduction of intraocular pressure.
Ganfort (bimatoprost 0.03% and timolol 0.5%)	Not available in United States	1 drop daily in the morning	
DuoTrav (travoprost 0.004% and timolol 0.5%)	Not available in United States	1 drop daily	
Cosopt (dorzolamide 2% and timolol 0.5%)	$130.80/10 mL	1 drop twice daily	
Combigan (brimonidine	Not available	1 drop twice daily	

0.2% and timolol 0.5%)	in United States		

[1] Average wholesale price (AWP, for AB-rated generic when available) for quantity listed. Source: *Red Book* Update, Vol. 28, No. 3, March 2009. AWP may not accurately represent the actual pharmacy cost because wide contractual variations exist among institutions.

[2] Many combination products containing antibacterials or antibacterials and corticosteroids are available.

[3] Little efficacy against gram-negative organisms (except *Neisseria*).

[4] Aplastic anemia has been reported with prolonged ophthalmic use.

[5] Also indicated for prophylaxis of neonatal conjunctivitis due to *Neisseria gonorrhoeae* or *Chlamydia trachomatis*.

[6] No gram-positive coverage.

[7] May produce rebound hyperemia and local reactions.

[8] Cross-sensitivity to aspirin and other nonsteroidal anti-inflammatory drugs.

[9] Long-term use increases intraocular pressure, causes cataracts and predisposes to bacterial, herpes simplex

virus, and fungal keratitis.

[10] Less likely to elevate intraocular pressure.

[11] Macular edema occurs in 30% of patients.

[12] Cardioselective ($_1$) -blocker.

[13] Teoptic is not available in the United States.

[14] Nonselective ($_1$ and $_2$) -blocker. Monitor all patients for systemic side effects, particularly exacerbation of asthma.

[15] Decreased night vision, headaches possible.

Instilling Medications

The patient is placed in a chair with head tilted back, both eyes open, and looking up. The lower lid is retracted slightly, and 2 drops of liquid are instilled into the lower cul-de-sac. The patient looks down while finger contact is maintained, so that the eyes are not squeezed shut. Ointments are instilled in the same general manner.

For self-medication, the same techniques are used except that medications are usually better instilled with the patient lying down.

Eye Bandage

Most eye bandages should be applied firmly enough to hold the lid securely against the cornea. An ordinary patch consisting of gauze-covered cotton is usually sufficient. Tape is applied diagonally from the forehead to the cheek.

Eyelid Taping

Eyelid taping, such as for corneal protection in facial palsy, is best achieved with 1-inch-width transparent plastic adhesive tape (eg, Transpore or even Sellotape) placed horizontally over the closed eyelids from the side of the nose to the temple.

Precautions in Management of Ocular Disorders

Use of Local Anesthetics

Unsupervised self-administration of local anesthetics is dangerous because the patient may further injure an anesthetized eye without knowing it. The drug may also interfere with the normal healing process.

Pupillary Dilation

Dilating the pupil can very occasionally precipitate acute glaucoma if the patient has a narrow anterior chamber angle and should be undertaken with caution if the anterior chamber is obviously shallow (readily determined by oblique illumination of the anterior segment of the eye). A short-acting mydriatic such as tropicamide should be used and the patient warned to report immediately if ocular discomfort or redness develops. Angle closure is more likely to occur if pilocarpine is used to overcome pupillary dilation than if the pupil is allowed to constrict naturally.

Corticosteroid Therapy

Repeated use of local corticosteroids presents several hazards: herpes simplex (dendritic) keratitis, fungal infection, open-angle glaucoma, and cataract formation. Furthermore, perforation of the cornea may occur when the corticosteroids are used for herpes simplex keratitis. Topical nonsteroidal anti-inflammatory agents are being used increasingly. The potential for causing or exacerbating systemic hypertension, diabetes mellitus, gastritis, osteoporosis, or glaucoma must always be borne in mind when systemic corticosteroids are prescribed, such as for uveitis or giant cell arteritis.

Jones R 3rd et al. Corticosteroid-induced ocular hypertension and glaucoma: a brief review and update of the literature. Curr Opin Ophthalmol. 2006 Apr;17(2):163–7. [PMID: 16552251]

Kersey JP et al. Corticosteroid-induced glaucoma: a review of the literature. Eye. 2006 Apr;20(4):407–16. [PMID: 15877093]

Contaminated Eye Medications

Ophthalmic solutions are prepared with the same degree of care as fluids intended for intravenous administration, but once bottles are opened there is always a risk of contamination, particularly with solutions of tetracaine, proparacaine, fluorescein, and any preservative-free preparations. The most dangerous is fluorescein, as this solution is frequently contaminated with *P aeruginosa*, which can rapidly destroy the eye. Sterile fluorescein filter paper strips are recommended for use in place of fluorescein solutions.

Whether in plastic or glass containers, eye solutions should not remain in use for long periods after the bottle is opened. Four weeks after opening is an absolute maximal time to use a solution containing preservatives before discarding. Preservative-free preparations should be kept refrigerated and discarded within 1 week after opening.

If the eye has been injured accidentally or by surgical trauma, it is of the greatest importance to use freshly opened bottles of sterile medications or single-use eyedropper units.

Toxic & Hypersensitivity Reactions to Topical Therapy

In patients receiving long-term topical therapy, local toxic or hypersensitivity reactions to the active agent or preservatives may develop, especially if there is inadequate tear secretion. Preservatives in contact lens cleaning solutions may produce similar problems. Burning and soreness are exacerbated by drop instillation or contact lens insertion; occasionally, fibrosis and scarring of the conjunctiva and cornea may occur.

An antibiotic instilled into the eye can sensitize the patient to that drug and cause an allergic reaction upon subsequent systemic administration.

Systemic Effects of Ocular Drugs

The systemic absorption of certain topical drugs (through the conjunctival vessels and lacrimal drainage system) must be considered when there is a systemic medical contraindication to the use of the drug. Ophthalmic solutions of the nonselective -blockers, eg, timolol, may worsen congestive heart failure or asthma. Phenylephrine eye drops may precipitate hypertensive crises and angina. Also to be considered are adverse interactions between systemically administered and ocular drugs. Using only 1 or 2 drops at a time and a few minutes of nasolacrimal occlusion or eyelid closure ensure maximum efficacy and decrease systemic side effects of topical agents.

Adverse Ocular Effects of Systemic Drugs

Systemically administered drugs produce a wide variety of adverse effects on the visual system. Table 7–3 lists the major examples.

Table 7–3. Adverse ophthalmic effects of systemic drugs.

Drug	**Possible Side Effects**
Respiratory drugs	
Oxygen	Retinopathy of prematurity.
Anticholinergic bronchodilators	Angle-closure glaucoma due to mydriasis, blurring of vision due to cycloplegia, dry eyes.
Sympathomimetic bronchodilators and decongestants	Angle-closure glaucoma due to mydriasis.
Cardiovascular system drugs	
Digitalis	Disturbance of color vision, photopsia.
Thiazides	Xanthopsia (yellow vision), myopia.
Carbonic anhydrase inhibitors (acetazolamide)	Stevens-Johnson syndrome, myopia.
Amiodarone	Corneal deposits (vortex keratopathy), optic neuropathy, thyroid

	ophthalmopathy.
Sildenafil	Ischemic optic neuropathy
Statins	Myasthenic syndrome
Gastrointestinal drugs	
Anticholinergic agents	Angle-closure glaucoma due to mydriasis, blurring of vision due to cycloplegia, dry eyes.
Central nervous system drugs	
Anticholinergic agents including preoperative medications	Angle-closure glaucoma due to mydriasis, blurring of vision due to cycloplegia, dry eyes.
Phenothiazines	Deposits of pigment in conjunctiva, cornea, lens, and retina, oculogyric crises.
Haloperidol	Capsular cataract.
Lithium carbonate	Proptosis, oculogyric crisis, nystagmus.
Amphetamines	Widening of palpebral fissure, blurring of vision due to mydriasis.
Monoamine oxidase inhibitors	Nystagmus.

Tricyclic agents	Angle-closure glaucoma due to mydriasis, blurring of vision due to cycloplegia.
Phenytoin	Nystagmus.
Neostigmine	Nystagmus, miosis.
Morphine	Miosis.
Diazepam	Nystagmus.
Topiramate	Angle-closure glaucoma, myopia.
Paroxetine	Angle-closure glaucoma.
Vigabatrin	Visual field constriction.
Obstetric drugs	
Sympathomimetic tocolytics	Angle-closure glaucoma due to mydriasis.
Hormonal agents	
Corticosteroids	Cataract (posterior subcapsular); susceptibility to viral (herpes simplex), bacterial, and fungal infections; steroid-induced glaucoma.
Female sex hormones	Retinal artery occlusion, retinal vein occlusion, papilledema, extraocular muscle palsies, ischemic optic

	neuropathy.
Tamoxifen	Crystalline retinal and corneal deposits, optic neuropathy.
Immunomodulators	
Cyclosporine	Posterior reversible leukoencephalopathy.
Tacrolimus	Optic neuropathy, posterior reversible leukoencephalopathy.
Antibacterials	
Chloramphenicol	Optic neuropathy.
Streptomycin	Optic neuropathy, Stevens-Johnson syndrome.
Tetracycline, doxycyline, minocycline	Papilledema.
Sulfonamides	Stevens-Johnson syndrome, myopia.
Ethambutol	Optic neuropathy.
Isoniazid	Optic neuropathy.
Antimalarial agents	
Chloroquine, hydroxychloroquine	Retinal degeneration principally involving the macula, keratopathy.
Amebicides	

Iodochlorhydroxyquin	Optic neuropathy.
Chemotherapeutic agents	
Chlorambucil	Optic neuropathy.
Fluorouracil	Lacrimal obstruction
Vincristine	Optic neuropathy.
Heavy metals	
Gold salts	Deposits in the cornea, conjunctiva, and lens.
Lead compounds	Optic neuropathy, papilledema, ocular palsies.
Chelating agents	
Penicillamine	Ocular pemphigoid, optic neuropathy, myasthenic syndrome.
Desferrioxamine	Retinopathy, optic neuropathy, lens opacity.
Oral hypoglycemic agents	
Chlorpropamide	Refractive error, Stevens-Johnson syndrome, optic neuropathy.
Vitamins	
Vitamin A	Papilledema.

Vitamin D	Band-shaped keratopathy.
Antirheumatic agents	
Salicylates	Subconjunctival or retinal hemorrhages, nystagmus.
Indomethacin	Corneal deposits.
Phenylbutazone	Retinal hemorrhages.
Dermatologic agents	
Retinoids (isotretinoin, tretinoin, acitretin, and etretinate)	Papilledema, blepharoconjunctivitis, corneal opacities, decreased contact lens tolerance, decreased dark adaptation, teratogenic ocular abnormalities.
Bisphosphonates	
Pamidronate	Scleritis, episcleritis, uveitis.
Alendronate	Scleritis, episcleritis, uveitis.

Hearing Loss

Essentials of Diagnosis

- Three main types of hearing loss: conductive, sensory, and neural.
- Most commonly due to cerumen impaction, transient eustachian tube dysfunction associated with upper respiratory tract infection, or age-related hearing loss.

Classification & Epidemiology

Conductive Hearing Loss

Conductive hearing loss results from dysfunction of the external or middle ear. There are four mechanisms, each resulting in impairment of the passage of sound vibrations to the inner ear: (1) obstruction (eg, cerumen impaction), (2) mass loading (eg, middle ear effusion), (3) stiffness effect (eg, otosclerosis), and (4) discontinuity (eg, ossicular disruption). Conductive losses in adults are most commonly due to cerumen impaction or transient eustachian tube dysfunction associated with upper respiratory tract infection. Persistent conductive losses usually result from chronic ear infection, trauma, or otosclerosis. Conductive hearing loss is usually correctable with medical or surgical therapy—or in some cases both.

Sensory Hearing Loss

Sensory hearing loss results from deterioration of the cochlea, usually due to loss of hair cells from the organ of Corti. Sensorineural losses in adults are common. The most common form is a gradually progressive, predominantly high-frequency loss with advancing age (presbyacusis). Additional common causes include excessive noise exposure, head trauma, and systemic diseases. An individual's genetic make-up influences all of these causes of sensory hearing loss. Sensory hearing loss is usually not correctable with medical or surgical therapy but often may be prevented or stabilized. An exception is a sudden sensory hearing loss, which may respond to corticosteroids if delivered within several weeks of onset.

Van Eyken E et al. The complexity of age-related hearing impairment: contributing environmental and genetic factors. Audiol Neurootol. 2007;12(6):345–58. [PMID: 17664866]

Neural Hearing Loss

Neural hearing loss occurs with lesions involving the eighth nerve, auditory nuclei, ascending tracts, or auditory cortex. It is the least common clinically recognized cause of hearing loss. Causes include acoustic neuroma, multiple sclerosis, and auditory neuropathy.

Vlastarakos PV et al. Auditory neuropathy: endocochlear lesion or temporal processing impairment? Implications for diagnosis and management. Int J Pediatr Otorhinolaryngol. 2008 Aug;72(8):1135–50. [PMID: 18502518]

Evaluation of Hearing (Audiology)

In a quiet room, the hearing level may be estimated by having the patient repeat aloud words presented in a soft whisper, a normal spoken voice, or a shout. A 512-Hz tuning fork is useful in differentiating conductive from sensorineural losses. In the **Weber test**, the tuning fork is placed on the forehead or front teeth. In conductive losses, the sound appears louder in the poorer-hearing ear, whereas in sensorineural losses it radiates to the better side. In the **Rinne test**, the tuning fork is placed alternately on the mastoid bone and in front of the ear canal. In conductive losses, bone conduction exceeds air conduction; in sensorineural losses, the opposite is true.

Formal audiometric studies are performed in a soundproofed room. Pure-tone thresholds in decibels (dB) are obtained over the range of 250–8000 Hz for both air and bone conduction. Conductive losses create a gap between the air and bone thresholds, whereas in sensorineural losses both air and bone thresholds are equally diminished. The threshold of normal hearing is roughly from 0 to 20 dB, which corresponds to the loudness of a soft whisper. Mild hearing loss is indicated by a threshold of 20–40 dB (soft spoken voice), moderate loss by a threshold of 40–60 dB (normal spoken voice), severe loss by a threshold of 60–80 dB (loud spoken voice), and profound loss by a threshold of 80 dB (shout). Speech discrimination measures the clarity of hearing, reported as percentage correct (90–100% is normal). The site of the lesion responsible for sensorineural loss (cochlea versus central auditory system) may be determined with auditory brainstem-evoked responses; however, an MRI scan is usually preferred method because it has both better sensitivity and specificity for evaluating central lesions.

Every patient who complains of a hearing loss should be referred for audiologic evaluation unless the cause is easily remediable (eg, cerumen impaction, otitis media). Since some forms of sudden hearing loss do not respond to treatment (corticosteroids) after several weeks, any new-onset hearing loss without obvious ear pathology needs an immediate audiometric referral. Routine audiologic screening is recommended for adults who have been exposed to potentially injurious levels of noise or in those who have reached the age of 65, after which screening evaluations may be done every few years.

Bagai A et al. Does this patient have hearing impairment? JAMA. 2006 Jan 25;295(4):416–28. [PMID: 16434632]

Hearing Rehabilitation

Patients with hearing loss not correctable by medical therapy may benefit from hearing amplification. Contemporary hearing aids are comparatively free of distortion and have been miniaturized to the point where they often may be contained entirely within the ear canal. To optimize the benefit, a hearing aid must be carefully selected to conform to the nature of the hearing loss. Digitally programmable hearing aids are now widely available and allow optimization of speech intelligibility and improved performance in difficult listening circumstances. Aside from hearing aids, many assistive devices are available to improve comprehension in individual and group settings, to help with hearing television and radio programs, and for telephone communication.

For patients with conductive loss or unilateral profound sensorineural loss, the bone-anchored hearing aid uses an oscillating post drilled into the mastoid, directly stimulating the ipsilateral cochlea (for conductive losses) or contralateral ear (profound unilateral hearing loss).

For patients with severe to profound sensory hearing loss, the cochlear implant—an electronic device that is surgically implanted into the cochlea to stimulate the auditory nerve—offers socially beneficial auditory rehabilitation to most adults with acquired deafness. New trends in cochlear implantation include its use for patients with only partial deafness, preserving residual hearing and allowing both acoustic and electrical hearing in the same ear, as well as bilateral cochlear implantation.

Diseases of the Auricle

Disorders of the auricle are for the most part dermatologic. Skin cancers due to sun exposure are common and may be treated with standard techniques. Traumatic auricular hematoma must be recognized and drained to prevent significant cosmetic deformity (cauliflower ear) or canal blockage resulting from dissolution of supporting cartilage. Similarly, cellulitis of the auricle must be treated promptly to prevent development of perichondritis and its resultant deformity. Relapsing polychondritis is a rheumatologic disorder often associated with recurrent, frequently bilateral, painful episodes of auricular erythema and edema. Treatment with corticosteroids may help forestall cartilage dissolution. Respiratory compromise may occur as a result of progressive involvement of the tracheobronchial tree. Chondritis and perichondritis may be differentiated from auricular cellulitis by sparing of involvement of the lobule, which does not contain cartilage.

Rapini RP et al. Relapsing polychondritis. Clin Dermatol. 2006 Nov–Dec;24(6):482–5. [PMID: 17113965]

Cerumen Impaction

Cerumen is a protective secretion produced by the outer portion of the ear canal. In most persons, the ear canal is self-cleansing. Recommended hygiene consists of cleaning the external opening with a washcloth over the index finger without entering the canal itself. In most cases, cerumen impaction is self-induced through ill-advised attempts at cleaning the ear. It may be relieved with detergent ear drops (eg, 3% hydrogen peroxide; 6.5% carbamide peroxide), mechanical removal, suction, or irrigation. Irrigation is performed with water at body temperature to avoid a vestibular caloric response. The stream should be directed at the ear canal wall adjacent to the cerumen plug. Irrigation should be performed only when the tympanic membrane is known to be intact.

Use of jet irrigators designed for cleaning teeth (eg, WaterPik) for wax removal should be avoided since they may result in tympanic membrane perforations. Following professional irrigation, the ear canal should be thoroughly dried (eg, by instilling isopropyl alcohol or using a hair blow-dryer on low-power setting) to reduce the likelihood of inducing external otitis. Specialty referral for cleaning under microscopic guidance is indicated when the impaction is frequently recurrent, has not responded to routine measures, or if the patient has a history of chronic otitis media or tympanic membrane perforation.

McCarter DF et al. Cerumen impaction. Am Fam Physician. 2007 May 15;75(10):1523–8. [PMID: 17555144]

Foreign Bodies

Foreign bodies in the ear canal are more frequent in children than in adults. Firm materials may be removed with a loop or a hook, taking care not to displace the object medially toward the tympanic membrane; microscopic guidance is helpful. Aqueous irrigation should not be performed for organic foreign bodies (eg, beans, insects), because water may cause them to swell. Living insects are best immobilized before removal by filling the ear canal with lidocaine.

Heim SW et al. Foreign bodies in the ear, nose, and throat. Am Fam Physician. 2007 Oct 15;76(8):1185–9. [PMID: 17990843]

External Otitis

Essentials of Diagnosis

- Painful erythema and edema of the ear canal skin.
- Often with purulent exudates.
- Persistent external otitis in the diabetic or immunocompromised patient may evolve into osteomyelitis of the skull base, often called malignant external otitis.

External otitis presents with otalgia, frequently accompanied by pruritus and purulent discharge. There is often a history of recent water exposure or mechanical trauma (eg, scratching, cotton applicators). External otitis is usually caused by gram-negative rods (eg, *Pseudomonas*, *Proteus*) or fungi (eg, *Aspergillus*), which grow in the presence of excessive moisture.

Examination reveals erythema and edema of the ear canal skin, often with a purulent exudate. Manipulation of the auricle often elicits pain. Because the lateral surface of the tympanic membrane is ear canal skin, it is often erythematous. However, in contrast to acute otitis media, it moves normally with pneumatic otoscopy. When the canal skin is very edematous, it may be impossible to visualize the tympanic membrane.

Fundamental to the treatment of external otitis is protection of the ear from additional moisture and avoidance of further mechanical injury by scratching.

Acidic otic antibiotic drops that contain either an aminoglycoside or fluoroquinolone antibiotic, with or without corticosteroids, are usually effective (eg, neomycin sulfate, polymyxin B sulfate, and hydrocortisone). Purulent debris filling the ear canal should be gently removed to permit entry of the topical medication. Drops should be used abundantly (five or more drops three or four times a day) to penetrate the depths of the canal. When substantial edema of the canal wall prevents entry of drops into the ear canal, a wick is placed to facilitate entry of the medication. In recalcitrant cases—particularly when cellulitis of the periauricular tissue has developed—oral fluoroquinolones (eg, ciprofloxacin, 500 mg twice daily for 1 week) are the drugs of choice because of their effectiveness against *Pseudomonas* species. Any case of persistent otitis externa in an immunocompromised or diabetic individual must be referred for specialty evaluation.

Rahman A et al. Pooled analysis of two clinical trials comparing the clinical outcomes of topical ciprofloxacin/dexamethasone otic suspension and polymyxin B/neomycin/hydrocortisone otic suspension for the treatment of acute otitis externa in adults and children. Clin Ther. 2007 Sep;29(9):1950–6. [PMID: 18035194]

Stone KE. Otitis externa. Pediatr Rev. 2007

Feb;28(2):77–8. [PMID: 17272526]

Pruritus

Pruritus of the external auditory canal, particularly at the meatus, is a common problem. While it may be associated with external otitis or with dermatologic conditions such as seborrheic dermatitis and psoriasis, most cases are self-induced either from excoriation or by overly zealous ear cleaning. To permit regeneration of the protective cerumen blanket, patients should be instructed to avoid use of soap and water or cotton swabs in the ear canal and avoid any scratching. Patients with excessively dry canal skin may benefit from application of mineral oil, which helps counteract dryness and repel moisture. When an inflammatory component is present, topical application of a corticosteroid (eg, 0.1% triamcinolone) may be beneficial. Symptomatic reduction of pruritus may also be obtained by use of oral antihistamines (eg, diphenhydramine, 25 mg orally at bedtime). Topical application of isopropyl alcohol promptly relieves ear canal pruritus in many patients.

Harth W et al. Topical tacrolimus treatment for chronic dermatitis of the ear. Eur J Dermatol. 2007 Sep–Oct;17(5):405–11. [PMID: 17673384]

Malignant External Otitis

Persistent external otitis in the diabetic or immunocompromised patient may evolve into osteomyelitis of the skull base, often called malignant external otitis. Usually caused by *Pseudomonas aeruginosa*, osteomyelitis begins in the floor of the ear canal and may extend into the middle fossa floor, the clivus, and even the contralateral skull base. The patient usually presents with persistent foul aural discharge, granulations in the ear canal, deep otalgia, and in advanced cases, progressive cranial nerve palsies involving nerves VI, VII, IX, X, XI, or XII. Diagnosis is confirmed by the demonstration of osseous erosion on CT and radionuclide scanning (see CT scan).

Fig.

Malignant external otitis. ***A:*** Axial CT scan reveals opacification of the left external canal and middle ear cavity. The anterior wall of the external canal and TMJ fossa are eroded *(arrow)* . The CT appearance is indistinguishable from that of squamous cell carcinoma. ***B, C:*** Axial CT scans (different patient) demonstrate an enhancing soft tissue mass *(arrow)* in the external auditory canal and bony erosion. Copyright © 1992 by The McGraw-Hill Companies, Inc.)

Treatment is medical, requiring prolonged antipseudomonal antibiotic administration, often for several months. Although intravenous therapy is often required, selected patients may be managed with ciprofloxacin (500–1000 mg orally twice daily), which has proved effective against many of the causative *Pseudomonas* strains. To avoid relapse, antibiotic therapy should be continued, even in the asymptomatic patient, until gallium scanning indicates a marked reduction in the inflammatory process. Surgical debridement of infected bone is reserved for cases of deterioration despite medical therapy.

Narozny W et al. Infectious skull base osteomyelitis–still a life-threatening disease. Otol Neurotol. 2006 Oct;27(7):1047–8. [PMID: 17006357]

Exostoses & Osteomas

Bony overgrowths of the ear canal are a frequent incidental finding and occasionally have clinical significance. Clinically, they present as skin-covered bony mounds in the medial ear canal obscuring the tympanic membrane to a variable degree. Solitary osteomas are of no significance as long as they do not cause obstruction or infection. Multiple exostoses, which are generally acquired from repeated exposure to cold water (eg, "surfer's ear") often progress and require surgical removal.

Hetzler DG. Osteotome technique for removal of symptomatic ear canal exostoses. Laryngoscope. 2007 Jan;117(1 Part 2 Suppl 113):1–E4. [PMID: 17220810]

Neoplasia

The most common neoplasm of the ear canal is squamous cell carcinoma (SCC). When an apparent otitis externa does not resolve on therapy, SCC should be suspected and biopsy performed. This disease carries a very high 5-year mortality rate because the tumor tends to invade the lymphatics of the cranial base and must be treated with wide surgical resection and radiation therapy. Adenomatous tumors, originating from the ceruminous glands, generally follow a more indolent course.

Ogawa K et al. Treatment and prognosis of squamous cell carcinoma of the external auditory canal and middle ear: a multi-institutional retrospective review of 87 patients. Int

J Radiat Oncol Biol Phys. 2007 Aug 1;68(5):1326–34. [PMID: 17446002]

Eustachian Tube Dysfunction

Essentials of Diagnosis

- Aural fullness.
- Fluctuating hearing.
- Discomfort with barometric pressure change.
- At risk for serous otitis media.

The tube that connects the middle ear to the nasopharynx—the eustachian tube—provides ventilation and drainage for the middle ear cleft. It is normally closed, opening only during swallowing or yawning. When eustachian tube function is compromised, air trapped within the middle ear becomes absorbed and negative pressure results. The most common causes of eustachian tube dysfunction are diseases associated with edema of the tubal lining, such as viral upper respiratory tract infections and allergy. The patient usually reports a sense of fullness in the ear and mild to moderate impairment of hearing. When the tube is only partially blocked, swallowing or yawning may elicit a popping or crackling sound. Examination may reveal retraction of the tympanic membrane and decreased mobility on pneumatic otoscopy. Following a viral illness, this disorder is usually transient, lasting days to weeks. Treatment with systemic and intranasal decongestants (eg, pseudoephedrine, 60 mg orally every 4 hours; oxymetazoline, 0.05% spray every 8–12 hours) combined with autoinflation by forced exhalation against closed nostrils may hasten relief. Autoinflation should not be recommended to patients with active intranasal infection, since this maneuver may precipitate middle ear infection. Allergic patients may also benefit from desensitization or intranasal corticosteroids (eg, beclomethasone dipropionate, two sprays in each nostril twice daily for 2–6 weeks). Air travel, rapid altitudinal change, and underwater diving should be avoided during an active phase of the disease.

Conversely, an overly patent eustachian tube, termed "patulous eustachian tube," is a relatively uncommon problem, though may be quite distressing. Typical complaints include fullness in the ear and autophony, an exaggerated ability to hear oneself breathe and speak. A patulous eustachian tube may develop during rapid weight loss, or it may be idiopathic. In contrast to a hypofunctioning eustachian tube, the aural pressure is often made worse by exertion and may diminish during an upper respiratory tract infection. Although physical examination is usually normal, respiratory excursions of the tympanic membrane may occasionally be detected during vigorous breathing. Treatment includes avoidance of decongestant products, insertion of a ventilating tube to reduce the outward stretch of the eardrum during phonation, and, rarely, surgical narrowing of the eustachian tube.

Poe DS. Diagnosis and management of the patulous eustachian tube. Otol Neurotol. 2007 Aug;28(5):668–77. [PMID: 17534202]

Poe DS et al. Laser eustachian tuboplasty: two-year results. Laryngoscope. 2007 Feb;117(2):231–7. [PMID: 17277615]

Serous Otitis Media

Essentials of Diagnosis

- Blocked eustachian tube remains for a prolonged period.
- Resultant negative pressure will result in transudation of fluid.

Prolonged eustachian tube dysfunction with resultant negative middle ear pressure may cause a transudation of fluid. This condition, known as serous otitis media, is especially common in children because their eustachian tubes are narrower and more horizontal in orientation than those in adults. Serous otitis media is less common in adults, in whom it usually occurs after an upper respiratory tract infection, with barotraumas, or with chronic allergic rhinitis. In any adult with persistent unilateral serous otitis media, nasopharyngeal carcinoma must be excluded. The tympanic membrane in serous otitis media is dull and hypomobile, occasionally accompanied by air bubbles in the middle ear and conductive hearing loss. The treatment of serous otitis media is similar to that for eustachian tube dysfunction. A short course of oral corticosteroids (eg, prednisone, 40 mg/d for 7 days) has been advocated by some clinicians, as have oral antibiotics (eg, amoxicillin, 250 mg orally three times daily for 7 days)—or even a combination of the two. The role of these regimens remains controversial, but they are probably of little lasting benefit.

When medication fails to bring relief after several months, a ventilating tube placed through the tympanic membrane may restore hearing and alleviate the sense of aural fullness. Endoscopically guided laser expansion of the nasopharyngeal orifice of the eustachian tube may improve function in recalcitrant cases.

Seibert JW et al. Eustachian tube function and the middle ear. Otolaryngol Clin North Am. 2006 Dec;39(6):1221–35. [PMID: 17097443]

Barotrauma

Persons with poor eustachian tube function (eg, congenital narrowness or acquired mucosal edema) may be unable to equalize the barometric stress exerted on the middle ear by air travel, rapid altitudinal change, or underwater diving. The problem is generally most acute during airplane descent, since the negative middle ear pressure tends to collapse and block the eustachian tube. Several measures are useful to enhance eustachian tube function and avoid otic barotrauma. The patient should be advised to swallow, yawn, and autoinflate frequently during descent, which may be painful if the eustachian tube collapses. Systemic decongestants (eg, pseudoephedrine, 60–120 mg) should be taken several hours before anticipated arrival time so that they will be maximally effective during descent. Topical decongestants such as 1% phenylephrine nasal spray should be administered 1 hour before arrival.

For acute negative middle ear pressure that persists on the ground, treatment includes decongestants and attempts at autoinflation. Myringotomy (creation of a small eardrum perforation) provides immediate relief and is appropriate in the setting of severe otalgia and hearing loss. Repeated episodes of barotrauma in persons who must fly frequently may be alleviated by insertion of ventilating tubes.

Underwater diving may represent an even a greater barometric stress to the ear than flying. The problem occurs most commonly during the descent phase, when pain develops within the first 15 feet if inflation of the middle ear via the eustachian tube has not occurred. Divers must descend slowly and equilibrate in stages to avoid the development of severely negative pressures in the tympanum that may result in hemorrhage (hemotympanum) or perilymphatic fistula. In the latter, the oval or round window ruptures, resulting in sensory hearing loss and acute vertigo. Emesis due to acute labyrinthine dysfunction can be very dangerous during an underwater dive. Sensory hearing loss or vertigo, which develops during the ascent phase of a saturation dive, may be the first (or only) symptom of decompression sickness. Immediate recompression will return intravascular gas bubbles to solution and restore the inner ear microcirculation. Patients should be warned to avoid diving when they have upper respiratory infections or episodes of nasal allergy. Tympanic membrane perforation is an absolute contraindication to diving, as the patient will experience an unbalanced thermal stimulus to the semicircular canals and may experience vertigo, disorientation, and even emesis. Finally, persons with only one hearing ear should be advised of the dangers of diving because of the potential risk of otologic injury.

Klingmann C et al. Barotrauma and decompression illness of the inner ear: 46 cases during treatment and follow-up. Otol Neurotol. 2007 Jun;28(4):447–54. [PMID:

17417111]

Acute Otitis Media

Essentials of Diagnosis

- Otalgia, often with an upper respiratory tract infection.
- Erythema and hypomobility of tympanic membrane.

General Considerations

Acute otitis media is a bacterial infection of the mucosally lined air-containing spaces of the temporal bone. Purulent material forms not only within the middle ear cleft but also within the pneumatized mastoid air cells and petrous apex. Acute otitis media is usually precipitated by a viral upper respiratory tract infection that causes eustachian tube obstruction. This results in accumulation of fluid and mucus, which becomes secondarily infected by bacteria. The most common pathogens both in adults and in children are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Streptococcus pyogenes*.

Clinical Findings

Acute otitis media is most common in infants and children, although it may occur at any age. Presenting symptoms and signs include otalgia, aural pressure, decreased hearing, and often fever. The typical physical findings are erythema and decreased mobility of the tympanic membrane. Occasionally, bullae will be seen on the tympanic membrane.

Rarely, when middle ear empyema is severe, the tympanic membrane can bulge outward. In such cases, tympanic membrane rupture is imminent. Rupture is accompanied by a sudden decrease in pain, followed by the onset of otorrhea. With appropriate therapy, spontaneous healing of the tympanic membrane occurs in most cases. When perforation persists, chronic otitis media may evolve. Mastoid tenderness often accompanies acute otitis media and is due to the presence of pus within the mastoid air cells. This alone does not indicate suppurative (surgical) mastoiditis. Frank swelling over the mastoid bone or the association of cranial neuropathies or central findings indicates severe disease requiring urgent care.

Treatment

The treatment of acute otitis media is specific antibiotic therapy, often combined with nasal decongestants. The first-choice oral antibiotic treatment is amoxicillin (20–40 mg/kg/d) or erythromycin (50 mg/kg/d) plus sulfonamide (150 mg/kg/d) for 10 days. Alternatives useful in resistant cases are cefaclor (20–40 mg/kg/d) or amoxicillin-clavulanate (20–40 mg/kg/d) combinations.

Tympanocentesis for bacterial (aerobic and anaerobic) and fungal culture may be performed by any experienced physician. A 20-gauge spinal needle bent 90 degrees to the hub attached to a 3-mL syringe is inserted through the inferior portion of the tympanic membrane. Interposition of a pliable connecting tube between the needle and syringe permits an assistant to aspirate without inducing movement of the needle. Tympanocentesis is useful for otitis media in immunocompromised patients and when infection persists or recurs despite multiple courses of antibiotics.

Surgical drainage of the middle ear (myringotomy) is reserved for patients with severe otalgia or when complications of otitis (eg, mastoiditis, meningitis) have occurred.

Recurrent acute otitis media may be managed with long-term antibiotic prophylaxis. Single daily oral doses of sulfamethoxazole (500 mg) or amoxicillin (250 or 500 mg) are given over a period of 1–3 months. Failure of this regimen to control infection is an indication for insertion of ventilating tubes.

Ramakrishnan K et al. Diagnosis and treatment of otitis media. Am Fam Physician. 2007 Dec 1;76(11):1650–8. [PMID: 18092706]

Chronic Otitis Media & Cholesteatoma

Chronic infection of the middle ear and mastoid generally develops as a consequence of recurrent acute otitis media, although it may follow other diseases and trauma. Perforation of the tympanic membrane is usually present. This may be accompanied by mucosal changes such as polypoid degeneration and granulation tissue and osseous changes such as osteitis and sclerosis. The bacteriology of chronic otitis media differs from that of acute otitis media. Common organisms include *P aeruginosa*, *Proteus* species, *Staphylococcus aureus*, and mixed anaerobic infections. The clinical hallmark of chronic otitis media is purulent aural discharge. Drainage may be continuous or intermittent, with increased severity during upper respiratory tract infection or following water exposure. Pain is uncommon except during acute exacerbations. Conductive hearing loss results from destruction of the tympanic membrane or ossicular chain, or both. The medical treatment of chronic otitis media includes regular removal of infected debris, use of earplugs to protect against water exposure, and topical antibiotic drops for exacerbations. The activity of ciprofloxacin against *Pseudomonas* may help to dry a chronically discharging ear when given in a dosage of 500 mg orally twice a day for 1–6 weeks.

Definitive management is surgical in most cases. Tympanic membrane repair may be accomplished with temporalis muscle fascia. Successful reconstruction of the tympanic membrane may be achieved in about 90% of cases, often with elimination of infection and significant improvement in hearing. When the mastoid air cells are involved by irreversible infection, they should be exenterated at the same time through a mastoidectomy.

Cholesteatoma is a special variety of chronic otitis media (Plate 57). The most common cause is prolonged eustachian tube dysfunction, with resultant chronic negative middle ear pressure that draws inward the upper flaccid portion of the tympanic membrane. This creates a squamous epithelium-lined sac, which—when its neck becomes obstructed—may fill with desquamated keratin and become chronically infected. Cholesteatomas typically erode bone, with early penetration of the mastoid and destruction of the ossicular chain. Over time they may erode into the inner ear, involve the facial nerve, and on rare occasions spread intracranially. Otoscopic examination may reveal an epitympanic retraction pocket, marginal tympanic membrane perforation that exudes keratin debris, or granulation tissue. The treatment of cholesteatoma is surgical marsupialization of the sac or its complete removal. This may require the creation of a "mastoid bowl" in which the ear canal and mastoid are joined into a large common cavity that must be periodically cleaned.

Complications of Otitis Media

Mastoiditis

Acute suppurative mastoiditis usually evolves following several weeks of inadequately treated acute otitis media. It is characterized by postauricular pain and erythema accompanied by a spiking fever. Radiography reveals coalescence of the mastoid air cells due to destruction of their bony septa. Initial treatment consists of intravenous antibiotics and myringotomy for culture and drainage. Failure of medical therapy indicates the need for surgical drainage (mastoidectomy).

Stähelin-Massik J et al. Mastoiditis in children: a prospective, observational study comparing clinical presentation, microbiology, computed tomography, surgical findings and histology. Eur J Pediatr. 2008 May;167(5):541–8. [PMID: 17668240]

Petrous Apicitis

The medial portion of the petrous bone between the inner ear and clivus may become a site of persistent infection when the drainage of its pneumatic cell tracts becomes blocked. This may cause foul discharge, deep ear and retro-orbital pain, and sixth nerve palsy (Gradenigo syndrome); meningitis may be a complication. Treatment is with prolonged antibiotic therapy (based on culture results) and surgical drainage via petrous apicectomy.

Hafidh MA et al. Otogenic intracranial complications. A 7-year retrospective review. Am J Otolaryngol. 2006 Nov–Dec;27(6):390–5. [PMID: 17084222]

Facial Paralysis

Facial palsy may be associated with either acute or chronic otitis media. In the acute setting, it results from inflammation of the seventh nerve in its middle ear segment, perhaps mediated through bacterially secreted neurotoxins. Treatment consists of myringotomy for drainage and culture, followed by intravenous antibiotics (based on culture results). The use of corticosteroids is controversial. The prognosis is excellent, with complete recovery in most cases.

Facial palsy associated with chronic otitis media usually evolves slowly due to chronic pressure on the seventh nerve in the middle ear or mastoid by cholesteatoma. Treatment requires surgical correction of the underlying disease. The prognosis is less favorable than for facial palsy associated with acute otitis media.

Kitsko DJ et al. Inner ear and facial nerve complications of acute otitis media, including vertigo. Curr Allergy Asthma Rep. 2007 Nov;7(6):444–50. [PMID: 17986375]

Sigmoid Sinus Thrombosis

Trapped infection within the mastoid air cells adjacent to the sigmoid sinus may cause septic thrombophlebitis. This is heralded by signs of systemic sepsis (spiking fevers, chills), at times accompanied by signs of increased intracranial pressure (headache, lethargy, nausea and vomiting, papilledema). Diagnosis can be made noninvasively by magnetic resonance venography. Primary treatment is with intravenous antibiotics (based on culture results). Surgical drainage with ligation of the internal jugular vein may be indicated when embolization is suspected.

Kuczkowski J et al. Lateral sinus thrombosis in chronic otitis media. Otol Neurotol. 2007 Oct;28(7):992–3. [PMID: 17909438]

Central Nervous System Infection

Otogenic meningitis is by far the most common intracranial complication of ear infection. In the setting of acute suppurative otitis media, it arises from hematogenous spread of bacteria, most commonly *H influenzae* and *S pneumoniae.* In chronic otitis media, it results either from passage of infections along preformed pathways such as the petrosquamous suture line or from direct extension of disease through the dural plates of the petrous pyramid.

Epidural abscesses arise from direct extension of disease in the setting of chronic infection. They are usually asymptomatic but may present with deep local pain, headache, and low-grade fever. They are often discovered as an incidental finding at surgery. Brain abscess may arise in the temporal lobe or cerebellum as a result of septic thrombophlebitis adjacent to an epidural abscess. The predominant causative organisms are *S aureus, S pyogenes*, and *S pneumoniae.* Rupture into the subarachnoid space results in meningitis and often death. (See Chapter 30: Common Problems in Infectious Diseases & Antimicrobial Therapy)

Hafidh MA et al. Otogenic intracranial complications. A

7-year retrospective review. Am J Otolaryngol. 2006 Nov–Dec;27(6):390–5. [PMID: 17084222]

Otosclerosis

Otosclerosis is a progressive disease with a marked familial tendency that affects the bony otic capsule. Lesions involving the footplate of the stapes result in increased impedance to the passage of sound through the ossicular chain, producing conductive hearing loss. This may be treated either through the use of a hearing aid or surgical replacement of the stapes with a prosthesis (stapedectomy). When otosclerotic lesions impinge on the cochlea ('cochlear otosclerosis'), permanent sensory hearing loss occurs. Some evidence suggests that hearing loss associated with cochlear otosclerosis may be stabilized by treatment with oral sodium fluoride over prolonged periods of time (Florical—8.3 mg sodium fluoride and 364 mg calcium carbonate—two tablets orally each morning).

Siddiq MA. Otosclerosis: a review of aetiology, management and outcomes. Br J Hosp Med (Lond). 2006 Sep;67(9):470–6. [PMID: 17017609]

Trauma to the Middle Ear

Tympanic membrane perforation may result from impact injury or explosive acoustic trauma (Plate 58). Spontaneous healing occurs in most cases. Persistent perforation may result from secondary infection brought on by exposure to water. Patients should be advised to wear earplugs while swimming or bathing during the healing period. Hemorrhage behind an intact tympanic membrane (hemotympanum) may follow blunt trauma or extreme barotrauma. Spontaneous resolution over several weeks is the usual course. When a conductive hearing loss greater than 30 dB persists for more than 3 months following trauma, disruption of the ossicular chain should be suspected. Middle ear exploration with reconstruction of the ossicular chain, combined with repair of the tympanic membrane when required, will usually restore hearing.

Plate 58.

Conoyer JM et al. Otologic surgery following ear trauma. Otolaryngol Head Neck Surg. 2007 Nov;137(5):757–61. [PMID: 17967641]

Middle Ear Neoplasia

Primary middle ear tumors are rare. Glomus tumors arise either in the middle ear (glomus tympanicum) or in the jugular bulb with upward erosion into the hypotympanum (glomus jugulare). They present clinically with pulsatile tinnitus and hearing loss. A vascular mass may be visible behind an intact tympanic membrane. Large glomus jugulare tumors are often associated with multiple cranial neuropathies, especially involving nerves VII, IX, X, XI, and XII. Treatment usually requires surgery, radiotherapy, or both. Pulsatile tinnitus thus warrants magnetic resonance angiography and venography to rule out a vascular mass.

Kaylie DM et al. Neurotologic surgery for glomus tumors. Otolaryngol Clin North Am. 2007 Jun;40(3):625–49. [PMID: 17544699]

Earache

Earache can be caused by a variety of otologic problems, but most commonly external otitis and acute otitis media. Differentiation of the two should be apparent by pneumatic otoscopy (see above relevant sections on otitis externa and otitis media). Pain out of proportion to the physical findings may be due to herpes zoster oticus, especially when vesicles appear in the ear canal or concha. Persistent pain and discharge from the ear suggest osteomyelitis of the skull base or cancer, and patients with these complaints should be referred for specialty evaluation.

Nonotologic causes of otalgia are numerous. The sensory innervation of the ear is derived from the trigeminal, facial, glossopharyngeal, vagal, and upper cervical nerves. Because of this rich innervation, referred otalgia is quite frequent. Temporomandibular joint dysfunction is a common cause of referred ear pain. Pain is exacerbated by chewing or psychogenic grinding of the teeth (bruxism) and may be associated with dental malocclusion. Management includes soft diet, local heat to the masticatory muscles, massage, nonsteroidal anti-inflammatory medications, and dental referral. Repeated episodes of severe lancinating otalgia may occur in glossopharyngeal neuralgia. Treatment with carbamazepine (100–300 mg orally every 8 hours) often confers substantial symptomatic relief. Severe glossopharyngeal neuralgia, which is refractory to medical management, may respond to microvascular decompression of the ninth cranial nerve. Infections and neoplasia that involve the oropharynx, hypopharynx, and larynx frequently cause otalgia. Persistent earache demands specialty referral to exclude cancer of the upper aerodigestive tract.

Charlett SD et al. Referred otalgia: a structured approach to diagnosis and treatment. Int J Clin Pract. 2007 Jun;61(6):1015–21. [PMID: 17504363]

Sensory Hearing Loss

Diseases of the cochlea result in sensory hearing loss, a condition that is usually irreversible. Most cochlear diseases result in bilateral symmetric hearing loss. The presence of unilateral or asymmetric sensorineural hearing loss suggests a lesion proximal to the cochlea. Lesions affecting the eighth cranial nerve and central auditory system are discussed in the section on neural hearing loss. The primary goals in the management of sensory hearing loss are prevention of further losses and functional improvement with amplification and auditory rehabilitation.

Presbyacusis

Presbyacusis, or age-related hearing loss, is the most frequent cause of sensory hearing loss and is progressive, predominantly high-frequency, and symmetrical. It is difficult to separate the various etiologic factors (eg, noise trauma, drug exposure) that may contribute to presbyacusis, but genetic predisposition and prior noise exposure appear to play an important role. Most patients notice a loss of speech discrimination that is especially pronounced in noisy environments. About 25% of people between the ages of 65 and 75 years and almost 50% of those over 75 experience hearing difficulties.

Van Eyken E et al. The complexity of age-related hearing impairment: contributing environmental and genetic factors. Audiol Neurootol. 2007;12(6):345–58. [PMID: 17664866]

Noise Trauma

Noise trauma is the second most common cause of sensory hearing loss. Sounds exceeding 85 dB are potentially injurious to the cochlea, especially with prolonged exposures. The loss typically begins in the high frequencies (especially 4000 Hz) and progresses to involve the speech frequencies with continuing exposure. Among the more common sources of injurious noise are industrial machinery, weapons, and excessively loud music. Personal music devices (eg, MP3 and CD players) used at excessive loudness levels may also be potentially injurious. In recent years, monitoring of noise levels in the workplace by regulatory agencies has led to preventive programs that have reduced the frequency of occupational losses. Individuals of all ages, especially those with existing hearing losses, should wear earplugs when exposed to moderately loud noises and specially designed earmuffs when exposed to explosive noises.

Daniel E. Noise and hearing loss: a review. J Sch Health.

2007 May;77(5):225–31. [PMID: 17430434]

Physical Trauma

Head trauma has effects on the inner ear similar to those of severe acoustic trauma. Some degree of sensory hearing loss may occur following simple concussion and is frequent after skull fracture. Deployment of air bags during an automobile accident has also been associated with hearing loss.

Ulug T et al. Contralateral labyrinthine concussion in temporal bone fractures. J Otolaryngol. 2006 Dec;35(6):380–3. [PMID: 17380831]

Ototoxicity

Ototoxic substances may affect both the auditory and vestibular systems. The most commonly used ototoxic medications are aminoglycosides; loop diuretics; and several antineoplastic agents, notably cisplatin. These medications may cause irreversible hearing loss even when administered in therapeutic doses. When using these medications, it is important to identify high-risk patients such as those with preexisting hearing losses or renal insufficiency. Patients simultaneously receiving multiple ototoxic agents are at particular risk owing to ototoxic synergy. Useful measures to reduce the risk of ototoxic injury include serial audiometry and monitoring of serum peak and trough levels and substitution of equivalent nonototoxic drugs whenever possible. Efforts are underway to develop strategies, known as ototoxic chemoprotection, using drugs that shield the inner ear from damage during ototoxic exposure.

It is possible for topical agents that enter the middle ear to be absorbed into the inner ear via the round window. When the tympanic membrane is perforated, use of potentially ototoxic ear drops (eg, neomycin, gentamicin) is best avoided.

Rizzi MD et al. Aminoglycoside ototoxicity. Curr Opin Otolaryngol Head Neck Surg. 2007 Oct;15(5):352–7. [PMID: 17823553]

Rybak LP. Mechanisms of cisplatin ototoxicity and progress in otoprotection. Curr Opin Otolaryngol Head Neck Surg. 2007 Oct;15(5):364–9. [PMID: 17823555]

Sudden Sensory Hearing Loss

Idiopathic sudden loss of hearing in one ear may occur at any age, but typically, it occurs in persons over age 20 years. The cause is unknown; however, one hypothesis is that it results from a viral infection or a sudden vascular occlusion of the internal auditory artery. Prognosis is mixed, with many patients suffering permanent deafness in the involved ear while others have complete recovery.

Prompt treatment with corticosteroids has been shown to improve the odds of recovery. A common regimen is oral prednisone, 80 mg/d, followed by a tapering dose over a 10-day period. Intratympanic administration of corticosteroids alone or in association with oral corticosteroids is increasingly being used for this problem and has been associated with more favorable prognosis in some reports. Because treatment appears to be most effective as close to the onset of the loss as possible, and appears not to be effective after 6 weeks, a prompt audiogram should be obtained in all patients who present with sudden hearing loss without obvious middle ear pathology.

Haynes DS et al. Intratympanic dexamethasone for sudden sensorineural hearing loss after failure of systemic therapy. Laryngoscope. 2007 Jan;117(1):3–15. [PMID: 17202923]

Wei B et al. Steroids for idiopathic sudden sensorineural hearing loss. Cochrane Database Syst Rev. 2006;(1):CD003998. [PMID: 16437471]

Hereditary Hearing Loss

Sensory hearing loss with onset during adult life often runs in families. The mode of inheritance may be either autosomal dominant or recessive. The age at onset, the rate of progression of hearing loss, and the audiometric pattern (high-frequency, low-frequency, or flat) can often be predicted by studying family members. In recent years, great strides have been made in identifying the molecular genetic errors associated with hereditary hearing loss. The connexin-26 mutation, the most common cause of genetic deafness, may be tested clinically. Hearing loss is also frequently found in hereditary mitochondrial disorders. Progress is being made toward the development of methods to restore lost hair cells in genetic and other forms of deafness via gene therapy or stem cell–mediated techniques.

Kochhar A et al. Clinical aspects of hereditary hearing loss. Genet Med. 2007 Jul;9(7):393–408. [PMID: 17666886]

Richardson RT et al. Inner ear therapy for neural preservation. Audiol Neurootol. 2006;11(6):343–56. [PMID: 16988498]

Autoimmune Hearing Loss

Sensory hearing loss may be associated with a wide array of systemic autoimmune disorders such as systemic lupus erythematosus, Wegener granulomatosis, and Cogan syndrome (hearing loss, keratitis, aortitis). The loss is most often bilateral and progressive. The hearing level often fluctuates, with periods of deterioration alternating with partial or even complete remission. The tendency is for the gradual evolution of permanent hearing loss, which usually stabilizes with some remaining auditory function but occasionally proceeds to complete deafness. Vestibular dysfunction, particularly dysequilibrium and postural instability, may accompany the auditory symptoms. A syndrome resembling Meniere disease may also occur with intermittent attacks of severe vertigo.

In many cases, the autoimmune pattern of audiovestibular dysfunction presents in the absence of recognized systemic autoimmune disease. Use of laboratory tests to screen for autoimmune disease (eg, antinuclear antibody, rheumatoid factor, erythrocyte sedimentation rate) may be informative. Specific tests of immune reactivity against inner ear antigens (anticochlear antibodies, lymphocyte transformation tests) are available but are currently of interest for research purposes only, demonstrating limited clinical value to date. Responsiveness to oral corticosteroid treatment is helpful in making the diagnosis and constitutes first-line therapy. If stabilization of hearing becomes dependent on long-term corticosteroid use, steroid-sparing immunosuppressive regimens may become necessary.

Agrup C et al. Immune-mediated inner-ear disorders in neuro-otology. Curr Opin Neurol. 2006 Feb;19(1):26–32. [PMID: 16415674]

Bovo R et al. Immune-mediated inner ear disease. Acta Otolaryngol. 2006 Oct;126(10):1012–21. [PMID: 16923703]

Tinnitus

Tinnitus is the perception of abnormal ear or head noises. Persistent tinnitus often, though not always indicates the presence of sensory hearing loss. Intermittent periods of mild, high-pitched tinnitus lasting seconds to minutes are common in normal-hearing persons. When severe and persistent, tinnitus may interfere with sleep and the ability to concentrate, resulting in considerable psychological distress.

The most important treatment of tinnitus is avoidance of exposure to excessive noise, ototoxic agents, and other factors that may cause cochlear damage. Masking the tinnitus with music or through amplification of normal sounds with a hearing aid may also bring some relief. Among the numerous drugs that have been tried, oral antidepressants (eg, nortriptyline at an initial dosage of 50 mg orally at bedtime) have proved to be the most effective. Habituation techniques, such as tinnitus retraining therapy, and masking techniques may prove beneficial in those with refractory symptoms. Transcranial magnetic stimulation of the central auditory system has recently been shown to improve symptoms in some patients.

Pulsatile tinnitus—often described by the patient as listening to one's own heartbeat—should be distinguished from tonal tinnitus. Although often ascribed to conductive hearing loss, this symptom may be far more serious and may indicate a vascular abnormality such as glomus tumor, venous sinus stenosis, carotid vaso-occlusive disease, arteriovenous malformation, or aneurysm. Magnetic resonance angiography and venography should be considered to establish the diagnosis.

In contrast, a staccato "clicking" tinnitus may result from middle ear muscle spasm, sometimes associated with palatal myoclonus. The patient typically perceives a rapid series of popping noises, lasting seconds to a few minutes, accompanied by a fluttering feeling in the ear.

Liyanage SH et al. Pulsatile tinnitus. J Laryngol Otol.

2006 Feb;120(2):93–7. [PMID: 16359136]

Hyperacusis

Excessive sensitivity to sound may occur in normal-hearing individuals either for psychological reasons, in association with ear disease, or following noise trauma. Patients with cochlear dysfunction commonly experience "recruitment," an abnormal sensitivity to loud sounds despite a reduced sensitivity to softer ones. Fitting hearing aids and other amplification devices to patients with recruitment requires use of compression circuitry to avoid uncomfortable overamplification. For normal-hearing individuals with hyperacusis, use of an earplug in noisy environments may be beneficial, though attempts should be made at habituation.

Hiller W et al. Factors influencing tinnitus loudness and annoyance. Arch Otolaryngol Head Neck Surg. 2006 Dec;132(12):1323–30. [PMID: 17178943]

Vertigo

Essentials of Diagnosis

- Either a sensation of motion when there is no motion or an exaggerated sense of motion in response to a given bodily movement.
- Duration of discrete vertiginous events is key to diagnosis.

- Must differentiate peripheral from central etiologies of vestibular dysfunction.
- Peripheral: Onset is sudden; often associated with tinnitus and hearing loss; horizontal nystagmus may be present.
- Central: Onset is gradual; no associated auditory symptoms.
- Evaluation includes audiogram and electronystagmography (ENG) or videonystagmography (VNG).

Clinical Findings

Symptoms and Signs

Vertigo is the cardinal symptom of vestibular disease. It is either a sensation of motion when there is no motion or an exaggerated sense of motion in response to a given bodily movement. While vertigo is typically experienced as a distinct "spinning" sensation, it may also present as a sense of tumbling or of falling forward or backward. It should be distinguished from imbalance, light-headedness, and syncope, all of which are nonvestibular in origin. The vertigo that results from peripheral vestibulopathy is usually of sudden onset, may be so severe that the patient is unable to walk or stand, and is frequently accompanied by nausea and vomiting. Tinnitus and hearing loss may be associated and provide strong support for a peripheral (ie, otologic) origin.

A thorough history will often narrow down, if not confirm the diagnosis. Critical elements of the history include the duration of the discrete vertiginous episodes (seconds, minutes to hours, or days), and associated symptoms. Triggers should also be sought, including diet (eg, high salt in the case of Ménière disease), stress, fatigue, and bright lights (eg, migraine-associated dizziness).

The physical examination of the patient with vertigo includes evaluation of the ears, eye motion in response to head turning and observation for nystagmus, cranial nerve examination, and Romberg testing. In acute peripheral lesions, nystagmus is usually horizontal with a rotatory component; the fast phase usually beats away from the diseased side. Visual fixation tends to inhibit nystagmus except in very acute peripheral lesions or with central nervous system disease. Dix-Hallpike testing (quickly lowering the patient to the supine position with the head extending over the edge and placed 30 degrees lower than the body, turned either to the left or right) will elicit a delayed onset (~10 sec) fatiguable nystagmus in cases of benign positional vertigo. Nonfatigable nystagmus in this position indicates a central etiology for the dizziness.

Since visual fixation often suppresses observed nystagmus, many of these maneuvers are performed with Frenzel goggles, which prevent visual fixation, and often bring out subtle forms of nystagmus. The Fukuda test, in which the patient consistently rotates when walking in place with eyes closed, can also demonstrate vestibular asymmetry.

In contrast to peripheral forms of vertigo, dizziness arising from central etiologies tends to develop gradually and then become progressively more severe and debilitating. Nystagmus is not always present but can occur in any direction and may be dissociated in the two eyes. The associated nystagmus is often nonfatigable, vertical rather than horizontal in orientation, without latency, and unsuppressed by visual fixation. ENG is useful in documenting these characteristics. The evaluation of central audiovestibular dysfunction requires imaging of the brain with MRI.

Episodic vertigo can occur in patients with diplopia from external ophthalmoplegia and is maximal when the patient looks in the direction where the separation of images is greatest. Cerebral lesions involving the temporal cortex may also produce vertigo, which is sometimes the initial symptom of a seizure. Finally, vertigo may be a feature of a number of systemic disorders and can occur as a side effect of certain anticonvulsant, antibiotic, hypnotic, analgesic, and tranquilizing drugs or of alcohol.

Laboratory Findings

Laboratory investigations such as audiologic evaluation, caloric stimulation, ENG, or VNG, and MRI are indicated in patients with persistent vertigo or when central nervous system disease is suspected. Vestibular-evoked myogenic potentials (VEMPs) are increasingly becoming part of the diagnostic evaluation. These studies will help distinguish between central and peripheral lesions and to identify causes requiring specific therapy. ENG consists of objective recording of the nystagmus induced by head and body movements, gaze, and caloric stimulation. It is helpful in quantifying the degree of vestibular hypofunction and may help with the differentiation between peripheral and central lesions. Computer-driven rotatory chairs and posturography platforms offer additional diagnostic modalities from specialized centers.

Vertigo Syndromes Due to Peripheral Lesions

Endolymphatic Hydrops (Ménière Syndrome)

The cause of Ménière syndrome is unknown. Distention of the endolymphatic compartment of the inner ear is a pathologic finding and thought to be part of the pathogenesis of the disorder. Although a precise cause of hydrops cannot be established in most cases, two known causes are syphilis and head trauma. The classic syndrome consists of episodic vertigo, with discrete vertigo spells lasting 20 minutes to several hours in association with fluctuating low-frequency sensorineural hearing loss, tinnitus (usually low-tone and "blowing" in quality), and a sensation of aural pressure. These symptoms in the absence of hearing fluctuations suggests migraine-associated dizziness. Symptoms wax and wane as the endolymphatic pressure rises and falls. Caloric testing commonly reveals loss or impairment of thermally induced nystagmus on the involved side. Primary treatment involves a low salt diet and diuretics (eg, acetazolamide). In refractory cases, patients may undergo intratympanic corticosteroid injections, endolymphatic sac decompression or vestibular ablation either through transtympanic gentamicin, vestibular nerve section, or surgical labyrinthectomy.

Wittner S. Diagnosis and treatment Meniere's disease. JAAPA. 2006 May;19(5):34–9. [PMID: 16722043]

Labyrinthitis

Patients with labyrinthitis suffer from acute onset of continuous, usually severe vertigo lasting several days to a week, accompanied by hearing loss and tinnitus. During a recovery period that lasts for several weeks, the vertigo gradually improves. Hearing may return to normal or remain permanently impaired in the involved ear. The cause of labyrinthitis is unknown. Treatment consists of antibiotics if the patient is febrile or has symptoms of a bacterial infection, and supportive care. Vestibular suppressants are useful during the acute phase of the attack (eg, diazepam or meclizine) but should be discontinued as soon as feasible to avoid long-term dysequilibrium from inadequate compensation.

Pullen RL Jr. Spin control: caring for a patient with inner ear disease. Nursing. 2006 May;36(5):48–51. [PMID: 16670600]

Benign Paroxysmal Positioning Vertigo

Patients suffering from recurrent spells of vertigo, lasting under several minutes per spell, associated with changes in head position (often provoked by rolling over in bed), usually have benign paroxysmal positioning vertigo. The term "positioning vertigo" is more accurate than "positional vertigo" because it is provoked by changes in head position rather than by the maintenance of a particular posture.

The typical symptoms of positioning vertigo occur in clusters that persist for several days. There is a brief (10–15 sec) latency period following a head movement before symptoms develop, and the acute vertigo subsides within 10–60 seconds, though the patient may remain imbalanced for several hours. Constant repetition of the positional change leads to habituation. Since some central nervous system disorders can mimic BPPV (eg, vertebrobasilar insufficiency), recurrent cases warrant MRI scanning of the head. In central lesions, there is no latent period, fatigability, or habituation of the symptoms and signs. Treatment of BPPV involves physical therapy protocols (eg, the Epley maneuver or Brandt-Daroff exercises), based on the theory that peripheral positioning vertigo results from free-floating otoconia within a semicircular canal.

Kovar M et al. Diagnosing and treating benign paroxysmal positional vertigo. J Gerontol Nurs. 2006 Dec;32(12):22–9. [PMID: 17190403]

Vestibular Neuronitis

In vestibular neuronitis, a paroxysmal, usually single attack of vertigo occurs without accompanying impairment of auditory function and will persist for several days to a week before gradually clearing. During the acute phase, examination reveals nystagmus and absent responses to caloric stimulation on one or both sides. The cause of the disorder is unclear though presumed to be viral. Treatment consists of supportive care, including diazepam or meclizine during the acute phases of the vertigo only, followed by vestibular therapy if the patient does not completely compensate.

Huppert D et al. Low recurrence rate of vestibular neuritis: a long-term follow-up. Neurology. 2006 Nov 28;67(10):1870–1. [PMID: 17130428]

Traumatic Vertigo

The most common cause of vertigo following head injury is labyrinthine concussion. Symptoms generally diminish within several days but may linger for a month or more. Basilar skull fractures that traverse the inner ear usually result in severe vertigo lasting several days to a week and deafness in the involved ear. Chronic posttraumatic vertigo may result from cupulolithiasis. This occurs when traumatically detached statoconia (otoconia) settle on the ampulla of the posterior semicircular canal and cause an excessive degree of cupular deflection in response to head motion. Clinically, this presents as episodic positioning vertigo. Treatment consists of supportive care and vestibular suppressant medication (diazepam or meclizine) during the acute phase of the attack and vestibular therapy.

Hoffer ME et al. Posttraumatic balance disorders. Int Tinnitus J. 2007;13(1):69–72. [PMID: 17691667]

Perilymphatic Fistula

Leakage of perilymphatic fluid from the inner ear into the tympanic cavity via the round or oval window is often discussed as a cause of vertigo and sensory hearing loss but is actually very rare. Most cases result from either physical injury (eg, blunt head trauma, hand slap to ear); extreme barotrauma during airflight, scuba diving, etc; or vigorous Valsalva maneuvers (eg, during weight lifting). Treatment may require middle ear exploration and window sealing with a tissue graft; however, this is seldom indicated without a clear-cut history of a precipitating traumatic event.

Alharethy SE. Oval window perilymph fistula caused by accidental stapedectomy during ear toilet. Saudi Med J. 2008 Jun;29(6):910–2. [PMID: 18521478]

Cervical Vertigo

Position receptors located in the facets of the cervical spine are important physiologically in the coordination of head and eye movements. Cervical proprioceptive dysfunction is a common cause of vertigo triggered by neck movements. This disturbance often commences after neck injury, particularly hyperextension. An association also exists with degenerative cervical spine disease. Although symptoms vary, vertigo may be triggered by assuming a particular head position as opposed to moving to a new head position (the latter typical of labyrinthine dysfunction). Management consists of neck movement exercises to the extent permitted by orthopedic considerations.

Endo K et al. Cervical vertigo and dizziness after whiplash injury. Eur Spine J. 2006 Jun;15(6):886–90. [PMID: 16432749]

Migrainous Vertigo

Episodic vertigo is frequently associated with a migraine type of headache. Most commonly, the vertigo is temporally related to the headache and lasts up to several hours. Some patients experience a positioning vertigo pattern. Occasionally, vertigo occurs independently of the head pain. It may appear identical to Meniere disease but without associated hearing loss or tinnitus. The importance of recognizing this association is that antimigraine pharmacotherapy often relieves the vestibular symptoms; other treatments include dietary changes and migraine prophylaxis.

Eggers SD. Migraine-related vertigo: diagnosis and treatment. Curr Pain Headache Rep. 2007 Jun;11(3):217–26. [PMID: 17504649]

Vitkovic J et al. Neuro-otological findings in patients with migraine- and nonmigraine-related dizziness. Audiol Neurootol. 2007 Nov 29;13(2):113–122. [PMID: 18057875]

Superior Semicircular Canal Dehiscence

Deficiency in the bony covering of the superior semicircular canal may be associated with vertigo triggered by loud noise exposure and an apparent conductive hearing loss. Diagnosis is with coronal high-resolution CT scan and VEMPs. Surgically sealing the dehiscent canal can improve symptoms.

Zhou G et al. Clinical and diagnostic characterization of canal dehiscence syndrome: a great otologic mimicker. Otol Neurotol. 2007 Oct;28(7):920–6. [PMID: 17955609]

Vertigo Syndromes Due to Central Lesions

Central nervous system causes of vertigo include brainstem vascular disease, arteriovenous malformations, tumor of the brainstem and cerebellum, multiple sclerosis, and vertebrobasilar migraine. Vertigo of central origin often becomes unremitting and disabling. The associated nystagmus is often nonfatigable, vertical rather than horizontal in orientation, without latency, and unsuppressed by visual fixation. ENG is useful in documenting these characteristics. There are commonly other signs of brainstem dysfunction (eg, cranial nerve palsies; motor, sensory, or cerebellar deficits in the limbs) or of increased intracranial pressure. Auditory function is generally spared. The underlying cause should be treated.

Dieterich M. Central vestibular disorders. J Neurol. 2007 May;254(5):559–68. [PMID: 17417688]

Seemungal BM. Neuro-otological emergencies. Curr Opin Neurol. 2007 Feb;20(1):32–9. [PMID: 17215686]

Diseases of the Central Auditory & Vestibular Systems

Lesions of the eighth cranial nerve and central audiovestibular pathways produce neural hearing loss and vertigo (Table 8–1). One characteristic of neural hearing loss is deterioration of speech discrimination out of proportion to the decrease in pure tone thresholds. Another is auditory adaptation, wherein a steady tone appears to the listener to decay and eventually disappear. Auditory evoked responses are useful in distinguishing cochlear from neural losses and may give insight into the site of lesion within the central pathways.

Table 8–1. Common vestibular disorders: Differential

diagnosis based on classic presentations.

Duration of Typical Vertiginous Episodes	**Auditory Symptoms Present**	**Auditory Symptoms Absent**
Seconds	Perilymphatic fistula	Positioning vertigo (cupulolithiasis), vertebrobasilar insufficiency, cervical vertigo
Hours	Endolymphatic hydrops (Menière syndrome, syphilis)	Recurrent vestibulopathy, vestibular migraine
Days	Labyrinthitis, labyrinthine concussion	Vestibular neuronitis
Months	Acoustic neuroma, ototoxicity	Multiple sclerosis, cerebellar degeneration

The evaluation of central audiovestibular disorders usually requires imaging of the internal auditory canal, cerebellopontine angle, and brain with enhanced MRI.

Vestibular Schwannoma (Acoustic Neuroma)

Eighth cranial nerve schwannomas are among the most common intracranial tumors. Most are unilateral, but about 5% are associated with the hereditary syndrome, neurofibromatosis type 2, in which bilateral eighth nerve tumors may be accompanied by meningiomas and other intracranial and spinal tumors. These benign lesions arise within the internal auditory canal and gradually grow to involve the cerebellopontine angle, eventually compressing the pons and resulting in hydrocephalus. Their typical auditory symptoms are unilateral hearing loss with a deterioration of speech discrimination exceeding that predicted by the degree of pure tone loss. Nonclassic presentations, such as sudden unilateral hearing loss, are fairly common. Any individual with a unilateral or asymmetric sensorineural hearing loss should be evaluated for an intracranial mass lesion. Vestibular dysfunction more often takes the form of continuous dysequilibrium than episodic vertigo. Other lesions of the cerebellopontine angle such as meningioma and epidermoids may have similar audiovestibular manifestations. Diagnosis is made by enhanced MRI. Treatment consists of observation, microsurgical excision, or stereotactic radiotherapy, depending on such factors as patient age, underlying health, and size of the tumor at presentation.

Roehm PC et al. Management of acoustic neuromas in patients 65 years or older. Otol Neurotol. 2007 Aug;28(5):708–14. [PMID: 17667776]

Vascular Compromise

Vertebrobasilar insufficiency is a common cause of vertigo in the elderly. It is often triggered by changes in posture or extension of the neck. Reduced flow in the vertebrobasilar system may be demonstrated noninvasively through magnetic resonance angiography. Empiric treatment is with vasodilators and aspirin.

Vascular loops that impinge upon the brainstem root entry zone of cranial nerves have been shown to cause dysfunction. Widely recognized examples are hemifacial spasm and tic douloureux. It has been suggested that hearing loss, tinnitus, and disabling positioning vertigo may result from a vascular loop abutting the eighth cranial nerve, although this is controversial.

de Castro Junior NP et al. Sudden sensorineural hearing loss and vertigo associated with arterial occlusive disease: three case reports and literature review. Sao Paulo Med J. 2007 May 3;125(3):191–5. [PMID: 17923946]

Kim HA et al. Acute peripheral vestibular syndrome of a vascular cause. J Neurol Sci. 2007 Mar 15;254(1-2):99–101. [PMID: 17257625]

Multiple Sclerosis

Patients with multiple sclerosis may suffer from episodic vertigo and chronic imbalance. Hearing loss in this disease is most commonly unilateral and of rapid onset. Spontaneous recovery may occur.

Zeigelboim BS et al. High-frequency hearing threshold in adult women with multiple sclerosis. Int Tinnitus J. 2007;13(1):11–4. [PMID: 17691657]

Otologic Manifestations of AIDS

The otologic manifestations of AIDS are protean. The pinna and external auditory canal may be affected by Kaposi sarcoma as well as persistent and potentially invasive fungal infections, particularly due to *Aspergillus fumigatus*. The most common middle ear manifestation of

AIDS is serous otitis media due to eustachian tube dysfunction arising from adenoidal hypertrophy (HIV lymphadenopathy), recurrent mucosal viral infections, or an obstructing nasopharyngeal tumor (eg, lymphoma). For middle ear effusions, ventilating tubes are seldom helpful and may trigger profuse watery otorrhea. Acute otitis media is usually caused by the typical bacterial organisms that occur in nonimmunocompromised patients, although *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) otitis has been reported. Sensorineural hearing loss is common and in some cases appears to result from viral central nervous system infection. In cases of progressive hearing loss, it is important to evaluate for cryptococcal meningitis and syphilis. Acute facial paralysis due to herpes zoster infection (Ramsay Hunt syndrome) is quite common and follows a clinical course similar to that in nonimmunocompromised patients. Treatment is primarily with high-dose acyclovir (see Chapter 6: Dermatologic Disorders and Chapter 32: Viral & Rickettsial Infections). Corticosteroids may also be effective.

Prasad HK et al. HIV manifestations in otolaryngology. Am J Otolaryngol. 2006 May–Jun;27(3):179–85. [PMID: 16647982]

Viral Rhinitis (Common Cold)

Essentials of Diagnosis

- Clear rhinorrhea, hyposmia and nasal congestion.
- Associated symptoms, including malaise, headache, and cough.
- Erythematous, engorged nasal mucosa on exam.
- Absence of intranasal purulence.

Clinical Findings

The nonspecific symptoms of the ubiquitous common cold are present in the early phases of many diseases that affect the upper aerodigestive tract. Because there are numerous serologic types of rhinoviruses, adenoviruses, and other viruses, patients remain susceptible throughout life. These infections, while generally quite benign and self-limited, have been implicated in the development of more serious conditions, such as acute bacterial sinusitis, acute otitis media, asthma and cystic fibrosis exacerbation and bronchitis. Nasal congestion, decreased sense of smell, watery rhinorrhea, and sneezing accompanied by general malaise, throat discomfort and, occasionally, headache are typical in viral infections. Nasal examination usually shows erythematous, edematous mucosa and a watery discharge. The presence of purulent nasal discharge suggests bacterial rhinosinusitis.

Treatment

Despite ongoing research into viral chemotherapy, at this time, there are no effective antiviral therapies for either the prevention or treatment of viral rhinitis. There is a common misperception among patients that antibiotics are helpful. Supportive measures such as decongestants (pseudoephedrine, 30–60 mg every 4–6 hours or 120 mg twice daily) may provide some relief of rhinorrhea and nasal obstruction. Nasal sprays such as oxymetazoline or phenylephrine are rapidly effective. They should not be used for more than a few days at a time, since prolonged use leads to an almost addictive need to prevent rebound congestion from withdrawal of the drug called **rhinitis medicamentosa.** Treatment requires mandatory cessation of the sprays, and this is often extremely frustrating for patients. Topical intranasal corticosteroids (eg, flunisolide, 2 sprays in each nostril twice daily), intranasal anticholinergic (ipratropium 0.06% nasal spray, 2–3 sprays every 8 hours as needed) or a short tapering course of oral prednisone may help during the process of withdrawal.

Complications

Other than eustachian tube dysfunction or transient middle ear effusion, complications of viral rhinitis are unusual. Secondary bacterial rhinosinusitis may occur and is suggested by persistence of symptoms beyond a week accompanied both by purulent green or yellow nasal secretions and unilateral facial or tooth pain. (See Acute Bacterial Rhinosinusitis, below.)

Doyle WJ et al. Use of diagnostic algorithms and new technologies to study the incidence and prevalence of viral upper respiratory tract infections and their complications in high risk populations. Curr Opin All Clin Immunol. 2007 Feb;7(1):11–16. [PMID: 17218805]

Patick AK. Rhinovirus chemotherapy. Antiviral Res. 2006 Sep;71(2–3):391–6. [PMID: 16675037]

Acute Bacterial Rhinosinusitis (Sinusitis)

Essentials of Diagnosis

- Purulent yellow-green nasal discharge or expectoration.
- Facial pain or pressure over the affected sinus or sinuses.
- Nasal obstruction.
- Acute onset of symptoms (between 1 and 4 week duration).
- Associated symptoms, including cough, malaise, fever, and headache.

General Considerations

Acute sinus infections are uncommon compared with viral rhinitis, but they still affect nearly 20 million Americans annually, accounting for over 2 billion dollars in health care expenditures for sinusitis annually. When chronic sinus infection is included, the cost rises to at least 5.8 billion dollars annually. Such infections are often associated with inflammation of the mucosal of the nasal cavity near the drainage pores of the sinuses. To acknowledge this inflammation as a major component of the disease and to differentiate it from such processes as allergic or acute viral rhinitis, otolaryngologists prefer the term "bacterial rhinosinusitis."

Acute bacterial rhinosinusitis usually is a result of impaired mucociliary clearance and obstruction of the osteomeatal complex, or sinus "pore." Edematous mucosa causes obstruction of the complex, resulting in the accumulation of mucous secretion in the sinus cavity that becomes secondarily infected by bacteria. The largest of these osteomeatal complexes is deep to the middle turbinate in the middle meatus. This complex is actually a confluence of complexes draining the maxillary, ethmoid, and frontal sinuses. The sphenoid drains from a separate complex between the septum and superior turbinate.

The typical pathogens of bacterial sinusitis are the same as those that cause acute otitis media: *S pneumoniae*, other streptococci, *H influenzae* and, less commonly, *S aureus* and *Moraxella catarrhalis*. Pathogens vary regionally in both prevalence and drug resistance. It should be kept in mind that about 25% of healthy asymptomatic individuals may, if sinus aspirates are cultured, harbor such bacteria as well. Understanding of the anatomy, pathogenesis and microbiology of acute bacterial rhinosinusitis can help the clinician afford the most expeditious and cost-effective diagnosis and treatment while avoiding serious complications.

Clinical Findings

Symptoms and Signs

The maxillary sinus, the largest of the paranasal sinuses, is the most commonly affected sinus. Unilateral facial fullness, pressure and tenderness over the cheek are common symptoms, but may not be present in many cases. Pain may refer to the upper incisor and canine teeth via branches of the trigeminal nerve, which traverse the floor of the sinus. Purulent nasal drainage should be noted with nasal obstruction or facial pain (pressure), or both. Maxillary sinusitis may result from dental infection, and teeth that are tender should be carefully examined for signs of abscess. Removal of the diseased tooth or drainage of the periapical abscess typically resolves the sinus infection. Nonspecific symptoms include fever, malaise, halitosis, headache, hyposmia, and cough. Bacterial rhinosinusitis can be distinguished from viral rhinitis by persistence of symptoms more than 10 days after onset or worsening of symptoms within 10 days after initial improvement.

Acute ethmoiditis in adults is often accompanied by maxillary sinusitis and symptoms are similar to those described above. Localized ethmoid sinusitis may present with pain and pressure over the high lateral wall of the nose between the eyes that may radiate to the orbit.

Sphenoid sinusitis is usually seen in the setting of pansinusitis, or infection of all the paranasal sinuses on at least one side. The patient may complain of a headache "in the middle of the head" and often points to the vertex. Acute frontal sinusitis usually causes pain and tenderness of the forehead. This is most easily elicited by palpation of the orbital roof just below the medial end of the eyebrow.

Hospital-associated sinusitis is a form of acute bacterial rhinosinusitis that may present without any symptoms in the head and neck. It is a common source of fever in critically ill patients and is often associated with prolonged presence of a nasogastric tube causing inflammation of the nasal mucosa and osteomeatal complex obstruction. Pansinusitis on the side of the tube is common on imaging studies.

Imaging

It is usually possible to make the diagnosis of acute bacterial rhinosinusitis on clinical grounds alone. Although more sensitive than clinical examination, routine radiographs are not cost-effective and are not recommended by the Agency for Health Care Policy and Research or American Association of Otolaryngology Guidelines in the routine diagnosis of acute bacterial rhinosinusitis. They may, however, be helpful when clinically based criteria are difficult to evaluate or when symptoms of more serious infection are noted (see x-ray); (see x-ray).

When necessary, noncontrast, screening coronal CT scans are more cost-effective and provide more information than conventional sinus films. CT provides a rapid and effective means to assess all of the paranasal sinuses, identify areas of greater concern (such as bony dehiscence, periosteal elevation or maxillary tooth root exposure within the sinus), and speed appropriate therapy.

Occasionally, a CT scan may be indicated to exclude acute bacterial rhinosinusitis (see CT scan). While reasonably sensitive, CT scans are not specific. Swollen soft tissue and fluid may be difficult to distinguish when opacification of the sinus is present from other conditions, such as chronic rhinosinusitis, nasal polyposis, or mucus retention cysts. Sinus abnormalities can be seen in most patients with an upper respiratory infection, while bacterial rhinosinusitis develops in only 2%.

Fig.

Sinusitis. ***A:*** Axial CT section reveals opacification of the left maxillary sinus. ***B:*** Axial T2-weighted MR image (TR [equals] 2000 ms, TE [equals] 80 ms) in the same patient. There is a peripheral zone of high signal intensity representing thickened mucosa with submucosal fluid. The central zone reveals slightly lower signal intensity. The mucoproteinaceous secretions show variable signals depending on the protein content. (Reproduced, with permission, from Rao VM, Flanders AE, Tom BM: *MRI and CT Atlas of Correlative Imaging in Otolaryngology*. Originally published by Appleton & Lange. Copyright © 1992 by The McGraw-Hill Companies, Inc.)

If malignancy, intracranial extension or opportunistic infection is suspected, MRI with gadolinium should be ordered instead of, or in addition to, CT. MRI will distinguish tumor from fluid, inflammation, and inspissated mucus far better than CT, as well as better delineating tumor extent with respect to adjacent structures such as the orbit, skull base, and palate. Bone destruction can be demonstrated as well by MRI as by CT.

Treatment

All patients with acute bacterial rhinosinusitis should have careful evaluation of pain. Nonsteroidal anti-inflammatories are generally recommended. Sinus symptoms may be improved with oral or nasal decongestants (or both)—eg, oral pseudoephedrine, 30–120 mg per dose, up to 240 mg/d; nasal oxymetazoline, 0.05%, or xylometazoline, 0.05–0.1%, one or two sprays in each nostril every 6–8 hours for up to 3 days.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Two-thirds patients with acute bacterial rhinosinusitis will improve symptomatically within 2 weeks without the use of antibiotics. However, antibiotics may be considered when symptoms last more than 10–14 days or when symptoms (including fever; facial pain; and periorbital, facial, or forehead swelling) are severe. Administration of antibiotics does, however, reduce by 50% the incidence of clinical failure and, coupled with clinical criteria-based diagnosis, represents the most cost-effective treatment strategy. Double-blinded studies exist to support numerous antibiotic choices. A summary of recent national guidelines for the treatment of acute sinusitis can be found in Table 8–2.

Table 8–2. Oral antibiotic regimens for acute sinusitis.

Drug	**Dose**	**Duration**	**Notes**
First-line therapy			
Amoxicillin	1000 mg three times daily	7–10 days	
Trimethoprim-sulfamethoxazole	160/800 twice daily	7–10 days	Suitable in penicillin allergy
Doxycycline	200 mg once daily x 1 day, 100 mg twice daily thereafter	7–10 days	Suitable in penicillin allergy
First-line therapy after recent antibiotic use[1]			
Levofloxacin	500 mg once daily	10 days	
Amoxicillin-clavulanate	875 mg–125 mg twice daily	10 days	
Second-line therapy			
Amoxicillin-clavulanate	1000 mg–62.5 mg ER 2 tablets twice daily	10 days	If no improvement after 3 days on first-line

			therapy
Moxifloxacin	400 mg once daily	10 days	If no improvement after 3 days on first-line therapy
Telithromycin[2]	800 mg once daily	10 days	If no improvement after 10–14 days of first-line therapy

[1] Within last 4–6 weeks.

[2] Contraindicated in myasthenia gravis; recent reports of hepatic failure.

Adapted, with permission, from Marple BF et al. Acute bacterial rhinosinusitis: a review of U.S. treatment guidelines. Otolaryngol Head Neck Surg. 2006 Sep;135(3):341–8.

Selection of antibiotics is usually empiric and based on a number of factors including regional patterns of antibiotic resistance, antibiotic allergy, cost, and patient tolerance. Unless the patient is allergic to penicillin, amoxicillin should be used as the first-line agent. Treatment is usually for 10 days (or as stated above), although longer courses are sometimes required to prevent relapses. Macrolide therapy has been recommended as first-line therapy in patients with penicillin allergy.

Multidrug resistant *S pneumoniae* prevalence is growing in many urban areas of the United States as are -lactamase/ -lactam inhibitor producing strains of *H influenza* and *M catarrhalis.* In such regions, guidelines call for empiric use of amoxicillin-clavulanate or second- or third-generation cephalosporins. Fluoroquinolones are reserved for treatment failures or for patients with a recent history of antibiotic therapy for another infection. Recurrent sinusitis or sinusitis that does not appear to respond clinically warrants CT imaging and evaluation by a specialist.

Hospital-associated infections in critically ill patients are treated differently from community-acquired infections. Broad-spectrum antibiotic coverage for bacteria including *P aeruginosa, S aureus* (including methicillin-resistant strains) and anaerobes must be considered. Removal of the nasogastric tube and improved nasal hygiene (nasal saline sprays, humidification of supplemental nasal oxygen, and nasal decongestants) are critical interventions and often curative in mild cases without aggressive antibiotic use. Endoscopic or transantral cultures may help direct medical therapy in complicated cases.

Complications

Local complications of acute bacterial rhinosinusitis include orbital cellulitis and abscess, osteomyelitis, intracranial extension and cavernous sinus thrombosis.

Any change in the ocular examination in a patient with acute bacterial rhinosinusitis necessitates immediate CT imaging. Orbital complications typically occur by extension of ethmoid sinusitis through the lamina papyracea, a thin layer of bone that comprises the medial orbital wall. Extension in this area may cause orbital cellulitis leading to proptosis, gaze restriction, and orbital pain. Select cases are responsive to intravenous antibiotics with or without corticosteroids and should be managed in close conjunction with an ophthalmologist or otolaryngologist, or both. Extension through the lamina papyracea can also lead to subperiosteal abscess formation (orbital abscess). Such abscesses cause marked proptosis, ophthalmoplegia and pain with medial gaze. While some of these abscesses will respond to antibiotics, such findings should prompt an immediate referral to a specialist for consideration of decompression and evacuation. Failure to intervene quickly may lead to permanent visual impairment and "frozen globe."

Osteomyelitis requires prolonged antibiotics as well as removal of necrotic bone. The frontal sinus is most commonly affected, with bone involvement suggested by a tender puffy swelling of the forehead (Pott puffy tumor). Following treatment, secondary cosmetic reconstructive procedures may be necessary.

Intracranial complications of sinusitis can occur either through hematogenous spread, as in cavernous sinus thrombosis and meningitis, or by direct extension, as in epidural and intraparenchymal brain abscesses. Fortunately, they are rare today. Cavernous sinus thrombosis is heralded by ophthalmoplegia, chemosis, and visual loss. The diagnosis is most commonly confirmed by MRI and, when identified early, it typically responds to intravenous antibiotics. Frontal epidural and intracranial abscesses are often clinically silent, but may present with altered metal status, persistent fever, or severe headache.

When to Refer

Failure of acute bacterial rhinosinusitis to resolve after an adequate course of oral antibiotics may necessitate referral to an otolaryngologist for evaluation. Endoscopic cultures may direct further treatment choices. Nasal endoscopy and CT scan are indicated when symptoms persist longer than 4–12 weeks.

When to Admit

- Facial swelling and erythema indicative of facial cellulitis.

- Proptosis.
- Vision change or gaze abnormality indicative of orbital cellulitis.
- Abscess or cavernous sinus involvement.
- Mental status changes suggestive of intracranial extension.
- Immunocompromised status.

Nasal Vestibulitis

Inflammation of the nasal vestibule may result from folliculitis of the hairs that line this orifice and is usually the result of nasal manipulation or hair trimming. Systemic antibiotics effective against *S aureus* (such as dicloxacillin, 250 mg orally four times daily for 7–10 days) are indicated. Topical mupirocin or bacitracin (applied two or three times daily) may be a helpful addition and may prevent future occurrences. If recurrent, the addition of rifampin (10 mg/kg orally twice daily for the last 4 days of treatment) may eliminate the *S aureus* carrier state. If a furuncle exists, it should be incised and drained, preferably intranasally. Adequate treatment of these infections is important to prevent retrograde spread of infection through valveless veins into the cavernous sinus and intracranial structures.

Invasive Fungal Sinusitis

Invasive fungal sinusitis is rare and includes both rhinocerebral mucormycosis (*Mucor, Absidia,* and *Rhizopus sp.*) and other invasive fungal infections, such as *Aspergillus*. The fungus spreads rapidly through vascular channels and may be lethal if not detected early. Patients with mucormycosis almost invariably have a contributing factor that results in some degree of immunocompromise, such as diabetes mellitus, long-term corticosteroid therapy, or end-stage renal disease. Mucormycosis is more common, however, in patients who are profoundly immunocompromised for the treatment of hematologic malignancies. Occasional cases have been reported in patients with AIDS though *Aspergillus sp.* is more common in this setting. The initial symptoms may be similar to those of acute bacterial rhinosinusitis, although facial pain is often more severe. Nasal drainage is typically clear or straw-colored, rather than purulent, and visual symptoms may be noted at presentation in the absence of significant nasal findings. On examination, the pathognomic finding of mucormycosis is a black eschar on the middle turbinate. This finding is not universal and may be inapparent if the infection is deep or high within the nasal bones. Often the mucosa appears normal or simply pale and dry. Early diagnosis requires suspicion of the disease and nasal biopsy with silver stains, revealing broad nonseptate hyphae within tissues and necrosis with vascular occlusion. Because CT or MRI may initially show only soft tissue changes, biopsy and ultimate debridement should be based on the clinical setting rather than radiographic demonstration of bony destruction or intracranial changes.

Invasive fungal sinusitis represents a medical and surgical emergency. Once recognized, prompt wide surgical debridement and amphotericin B by intravenous infusion are indicated for patients with reversible immune deficiency. Lipid-based amphotericin B (Ambisome) may be used in patients who have renal insufficiency or in those in whom it develops secondary to nephrotoxic doses of nonlipid amphotericin. Other antifungals, including voriconazole and caspofungin, may be appropriate therapy depending on the speciation of the organism. There is evidence that suggests that iron chelator therapy may also be a useful adjunct. While necessary for any possibility of cure, surgical management often results in tremendous disfigurement and functional deficits. Even with early diagnosis and immediate appropriate intervention, the prognosis is guarded and often results in the loss of at least one eye. In persons with diabetes, the mortality rate is about 20%; in patients with renal failure, it is over 50%; in AIDS and hematologic malignancy, it is close to 100%.

Allergic Rhinitis

Essentials of Diagnosis

- Clear rhinorrhea, sneezing, tearing, eye irritation, and pruritus.

- Associated symptoms, including cough, bronchospasm, eczematous dermatitis.
- Environmental allergen exposure with presence of allergen specific IgE.

General Considerations

Allergic rhinitis is very common in the United States. Population studies have reported the prevalence as between 14% and 40% among Americans, with most consensus panels agreeing on 20%. The total costs to society is estimated as up to 6 billion dollars annually. Seasonal allergic rhinitis is most commonly caused by pollens and spores. Flowering shrub and tree pollens are most common in the spring, flowering plants and grasses in the summer, and ragweed and molds in the fall. Dust, household mites, air pollution, and pet dander may produce year-round symptoms, termed "perennial rhinitis."

Allergic rhinitis is caused by exposure to an airborne allergen in a predisposed individual. Activation of both humoral (B-cell) and cytotoxic (T-cell) immune responses with subsequent allergen-specific IgE responses causes release of inflammatory mediators. The response is increased as antigen is passed to regional lymph nodes for greater T-cell activation. Interleukin and cytokine release causes specific activation of mast cells, eosinophils, plasma cells, basophils and other T-cells. Many of these circulating cells then migrate into the nasal and ocular epithelium where they contribute directly to symptoms through proinflammatory mediators, including histamine, prostaglandins, and kinins.

Clinical Findings

The symptoms of "hay fever" are similar to those of viral rhinitis but are usually persistent and may show seasonal variation. Nasal symptoms are often accompanied by eye irritation, pruritus, conjunctival erythema, and excessive tearing. Many patients will note a strong family history of atopy or allergy.

The clinician should be careful to distinguish allergic rhinitis from nonallergic or vasomotor rhinitis. Vasomotor rhinitis is caused by increased sensitivity of the vidian nerve and is a common cause of clear rhinorrhea in the elderly. Often patients will report that they have troubling rhinorrhea in response to numerous nasal stimuli, including warm or cold air, odors or scents, light, or particulate matter.

On physical examination, the mucosa of the turbinates is usually pale or violaceous because of venous engorgement. This is in contrast to the erythema of viral rhinitis. Nasal polyps, which are yellowish boggy masses of hypertrophic mucosa, are associated with long-standing allergic rhinitis.

Treatment

Antihistamines

Treatment of allergic and perennial rhinitis has improved in recent years. Antihistamines offer temporary, but immediate, control of many of the most troubling symptoms of allergic rhinitis. Numerous over-the-counter antihistamines, such as brompheniramine or chlorpheniramine (4 mg orally every 6–8 hours, or 8–12 mg orally every 8–12 hours as a sustained-release tablet) and clemastine (1.34–2.68 mg orally twice daily) offer the benefit of reduced cost though usually associated with higher rates of drowsiness compared with the newer prescription antihistamines. Exceptions may be loratadine (10 mg orally once daily) and the minimally sedating cetirizine (10 mg orally once daily), which are now available over the counter. Other prescription oral H_1-receptor antagonists include fexofenadine (60 mg orally twice daily or 120 mg once daily) and desloratadine (5 mg orally once daily). Fexofenadine appears to be nonsedating; desloratadine is minimally sedating. Also shown to be effective in randomized trials are ebastine (10–20 mg orally once daily) and misolastine (10 mg once daily). Two H_1-receptor antagonist antihistamine nasal sprays have also been shown to be effective in randomized trials: levocabastine (0.2 mg twice daily) and azelastine (two sprays per nostril, 1.1 mg/d). Topical nasal sprays are particularly useful in patients who complain of side effects, mostly xerostomia and sedation, of oral antihistamines. Many patients who find initial benefit from an antihistamine complain that allergy symptoms eventually return after several months of use. In such patients, typically with perennial allergy problems, antihistamine tolerance seems to develop and alternating effective antihistamines periodically can control symptoms over the long term.

Intranasal Corticosteroids

Intranasal corticosteroid sprays have revolutionized the treatment of allergic rhinitis. Evidence-based literature reviews show that these are more effective—and frequently less expensive—than nonsedating antihistamines. Patients should be reminded that there may be a delay in onset of relief of 2 or more weeks. Corticosteroid sprays may also shrink hypertrophic nasal mucosa and nasal polyps, thereby providing an improved nasal airway and osteomeatal complex drainage. Because of this effect, intranasal corticosteroids are critical in treating allergy in patients prone to recurrent acute bacterial rhinosinusitis or chronic rhinosinusitis. There are many available preparations, including beclomethasone (42 mcg/spray twice daily per nostril), flunisolide (25 mcg/spray twice daily per nostril), mometasone furoate (200 mcg once daily per nostril), budesonide (100 mcg twice daily per nostril) and fluticasone propionate (200 mcg once daily per nostril). The latter two synthetic corticosteroids appear to have higher topical potencies and lipid solubility and reduced systemic bioavailability, suggesting possible practical advantages; however, in practice, all intranasal corticosteroids are considered equally effective. Probably the most critical factor is compliance with regular use and proper introduction into the nasal cavity. In order to deliver medication to the region of the middle meatus, proper application involves holding the bottle straight up with the head tilted forward and pointing the bottle toward the ipsilateral ear when spraying. Side effects are limited and the most annoying is epistaxis. Some experts believe that this is related to incorrect delivery to the nasal septum, rather than correct delivery to the region of the middle meatus.

Adjunctive Treatment Measures

In addition to intranasal corticosteroid sprays and antihistamines, including H_1-receptor antagonists, the literature supports the use of antileukotriene medications such as montelukast (10 mg/d orally) alone or with cetirizine (10 mg/d orally) or loratadine (10 mg/d orally). There are proinflammatory effects of cysteinyl leukotrienes in upper airway disease, including allergic rhinitis, and hyperplastic polyposis, and sinusitis. Improved nasal rhinorrhea, sneezing, and congestion are seen with the use of leukotriene receptor antagonists, often in conjunction with antihistamines. Cromolyn sodium and sodium nedocromil are also useful adjunct agents for allergic rhinitis. They work by stabilizing mast cells and preventing proinflammatory mediator release. They are not absorbed by the gastrointestinal tract but do function topically and have very few side effects. The most useful form of cromolyn is probably the ophthalmologic preparation; the nasal preparation is not nearly as effective as inhaled corticosteroids. Intranasal cromolyn is cleared rapidly and must be administered four times daily for continued relief of symptoms.

Intranasal anticholinergic agents, such as ipratropium bromide 0.03% or 0.06% sprays (42–84 mcg per nostril three times daily), may be helpful adjuncts when rhinorrhea is a major symptom. Ipratropium nasal sprays are not as effective as intranasal corticosteroids for treating allergic rhinitis but are useful for treating vasomotor rhinitis.

Avoiding or reducing exposure to airborne allergens is the most effective means of alleviating symptoms of allergic rhinitis. Depending on the allergen, this can be extremely difficult, however. Maintaining an allergen-free environment by covering pillows and mattresses with plastic covers, substituting synthetic materials (foam mattress, acrylics) for animal products (wool, horsehair), and removing dust-collecting household fixtures (carpets, drapes, bedspreads, wicker) is worth the attempt to help more troubled patients. Air purifiers and dust filters (such as Bionaire models) may also aid in maintaining an allergen-free environment. Nasal saline irrigations are a very useful adjunct in the treatment of allergic rhinitis to mechanically flush the allergens from the nasal cavity. Though debated, there is no clear benefit to hypertonic saline over commercially available normal saline preparations (eg, Ayr or Ocean Spray). When symptoms are extremely bothersome, a search for offending allergens may prove helpful. This can either be done by skin testing or by serum RAST testing by an allergist.

In some cases, allergic rhinitis symptoms are inadequately relieved by medication and avoidance measures. Often, such patients have a strong family history of atopy and may also have lower respiratory manifestations such as allergic asthma. Referral to an allergist may be appropriate in such cases for consideration of immunotherapy. This treatment course is quite involved, with proper identification of offending allergens, progressively increasing doses of allergen(s) and eventual maintenance dose administration over a period of 3–5 years. Immunotherapy has been proven to reduce circulating IgE levels in patients with allergic rhinitis and reduce the need for allergy medications. While oral allergen exposure is actively being investigated, currently the primary mode of allergen exposure is by subcutaneous injection. Treatments are given at a suitable medical facility with monitoring following treatment because of the risk of anaphylaxis during dose escalation. Local reactions are common and usually self-limited.

Olfactory Dysfunction

The physiology of olfaction is less well understood than that of the other special senses. The taste of foods is strongly affected by our sense of smell, and studies have shown a moderate correlation between taste discrimination ability and odor discrimination ability. In the past few years, discovery of the family of odorant receptor genes as well as inositol phosphate and cyclic nucleotide signaling pathways has led to a molecular basis of olfactory reception. Clinically, odorant molecules traverse the nasal vault to reach the cribriform area and become soluble in the mucus overlying the exposed dendrites of receptor cells. Anatomic blockage of the nasal cavity with subsequent airflow disruption is the most common cause of olfactory dysfunction (hyposmia or anosmia). Polyps, septal deformities, and nasal tumors may be the cause. Transient olfactory dysfunction often accompanies the common cold, nasal allergies, and perennial rhinitis through changes in the nasal and olfactory epithelium. About 20% of olfactory dysfunction is idiopathic, although it often follows a viral illness. Some have suggested administering large doses of vitamin A and zinc to such patients, although little evidence supports their use. Central nervous system neoplasms, especially those that involve the olfactory groove or temporal lobe, may affect olfaction and must be considered in patients with no other explanation for their hyposmia or other neurologic signs. Head trauma accounts for less than 5% of cases of hyposmia but is more commonly associated with anosmia. Absent, diminished, or distorted smell or taste has been reported in a wide variety of endocrine, nutritional, and nervous disorders. In particular, olfactory dysfunction in Parkinson disease and Alzheimer disease has been the subject of recent research. A great many medications have also been implicated in altering olfaction.

Evaluation of olfactory dysfunction should include a thorough history of systemic illnesses and medication use as well as a physical examination focusing on the nose and nervous system. Most clinical offices are not set up to test olfaction, but such tests may at times be worthwhile if only to assess whether a patient possesses any sense of smell at all. The University of Pennsylvania Smell Identification Test (UPSIT) is available commercially and is a simple, self-administered "scratch-and-sniff" test that is useful in differentiating hyposmia, anosmia, and malingering. Odor threshold can be tested at regional specialty centers using increasing concentrations of various odorants. In permanent hyposmia, counseling should be offered about seasoning foods with spices (eg, pepper) that stimulate the trigeminal as well as olfactory chemoreceptors, abuse of table salt as a seasoning, and safety issues such as the use of smoke alarms and electric rather than gas home appliances.

Epistaxis

Essentials of Diagnosis

- Bleeding from the unilateral anterior nasal cavity most commonly.
- Most cases may be successfully treated by direct pressure on the bleeding site for 15 minutes. When this is inadequate, topical sympathomimetics and various nasal tamponade methods are usually effective.
- Posterior, bilateral, or large volume epistaxis should be triaged immediately to a specialist in a critical care setting.

General Considerations

Epistaxis is an extremely common problem in the primary care setting. Predisposing factors include nasal trauma (nose picking, foreign bodies, forceful nose blowing), rhinitis, drying of the nasal mucosa from low humidity or supplemental nasal oxygen, deviation of the nasal septum, hypertension, atherosclerotic disease, hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome), inhaled nasal cocaine or other drug use, and alcohol use. Anticoagulation or antiplatelet medications may be associated with a higher incidence of epistaxis, more frequent recurrence of epistaxis, and greater difficulty controlling bleeding, but they do not cause epistaxis. Bleeding is most common in the anterior septum where a confluence of veins creates a superficial venous plexus (Kisselbach plexus).

Clinical Findings

It is important in all patients with epistaxis to consider underlying causes of the bleeding. Laboratory assessment of bleeding parameters may be indicated, especially in recurrent cases. Once the acute episode has passed, careful examination of the nose and paranasal sinuses to rule out neoplasia and hereditary hemorrhagic telangiectasia is wise.

Patients presenting with epistaxis often have higher blood pressures than control patients, but in many cases, blood pressure returns to normal following treatment of acute bleeding. Repeat evaluation for clinically significant hypertension and treatment should be performed following control of epistaxis and removal of any packing.

Treatment

Most cases of anterior epistaxis may be successfully treated by direct pressure on the site by compression of the nares continuously for 15 min (see illustration). Venous pressure is reduced in the sitting position, and slight leaning forward lessens the swallowing of blood. Short-acting topical nasal decongestants (eg, phenylephrine, 0.125–1% solution, one or two sprays), which act as vasoconstrictors, may also be helpful. When the bleeding does not readily subside, the nose should be examined, using good illumination and suction, in an attempt to locate the bleeding site. Topical 4% cocaine applied either as a spray or on a cotton strip serves both as an anesthetic and as a vasoconstricting agent. If cocaine is unavailable, a topical decongestant (eg, oxymetazoline) and a topical anesthetic (eg, tetracaine or lidocaine) provide equivalent results. When visible, the bleeding site may be cauterized with silver nitrate, diathermy, or electrocautery. A supplemental patch of Surgicel or Gelfoam may be helpful with a moisture barrier, such as petroleum-based ointment, to prevent drying and crusting.

Fig.

Anatomy of the nasal cavity, showing the location of the blood supply to the nasal septum. (Reproduced, with permission, from Chesnutt MS et al: *Office & Bedside Procedures*. McGraw-Hill, 1992.)

Occasionally, a site of bleeding may be inaccessible to direct control, or attempts at direct control may be unsuccessful. In such cases there are a number of alternatives. When the site of bleeding is anterior, a hemostatic sealant, pneumatic nasal tamponade, or anterior packing may suffice. There are a number of ways to do this, such as with several feet of lubricated iodoform packing systematically placed in the floor of the nose and then the vault of the nose, or with various manufactured products designed for nasal tamponade.

About 5% of nasal bleeding originates in the **posterior nasal cavity.** Such bleeds are more commonly associated with atherosclerotic disease and hypertension. If an anteriorly placed pneumatic nasal tamponade is unsuccessful, it may be necessary to consult an otolaryngologist for a pack to occlude the choana before placing a pack anteriorly (see illustration). In emergency settings, new double balloon packs (Epistat) may facilitate rapid control of bleeding with little or no mucosal trauma. Because such packing is uncomfortable, bleeding may persist, and vasovagal syncope is quite possible, hospitalization for monitoring and stabilization is indicated. Opioid analgesics are needed to reduce the considerable discomfort and elevated blood pressure caused by a posterior pack.

Fig.
Control of posterior epitaxis using rolled posterior pack. **A:** Flexible rubber catheter inserted and pack attached. **B:** Catheter removed and posterior pack drawn into position. C. Anterior pack installed "accordion-pleating" style and posterior pack tied in place over a bolster. (Reproduced, with permission, from Chesnutt MS et al: *Office & Bedside Procedures*. Surgical management of epistaxis, through ligation of the nasal arterial supply (internal maxillary artery and ethmoid arteries) is an alternative to posterior nasal packing. Endovascular embolization of the internal maxillary artery or facial artery is also quite effective and can allow very specific control of hemorrhage. Such alternatives are necessary when packing fails to control life-threatening hemorrhage. On very rare occasions, ligation of the external carotid artery may be necessary.

After control of epistaxis, the patient is advised to avoid straining and vigorous exercise for several days. Nasal saline should be applied to the packing frequently to keep the packing moist. Avoidance of hot or spicy foods and tobacco is also advisable, since these may cause nasal vasodilation. Avoiding nasal trauma, including nose picking, is an obvious necessity. Lubrication with petroleum jelly or bacitracin ointment and increased home humidity may also be useful ancillary measures. Finally, antistaphylococcal antibiotics are indicated to reduce the risk of toxic shock syndrome developing while the packing remains in place (at least 5 days).

When to Refer

Patients with recurrent epistaxis, large volume epistaxis, epistaxis that persists beyond 15 minutes of direct pressure, and episodic epistaxis with associated nasal obstruction should be referred to an otolaryngologist for endoscopic evaluation and possible imaging.

Nasal Trauma

The nasal pyramid is the most frequently fractured bone in the body. Fracture is suggested by crepitance or palpably mobile bony segments. Epistaxis and pain are common, as are soft tissue hematomas ("black eye"). It is important to make certain that there is no palpable step-off of the infraorbital rim, which would indicate the presence of a zygomatic complex fracture. Radiologic confirmation may at times be helpful but is not necessary in uncomplicated nasal fractures. It is also important to assess for possible concomitant additional facial, pulmonary, or intracranial injuries when the circumstances of injury are suggestive, as in the case of automobile and motorcycle accidents.

Treatment is aimed at maintaining long-term nasal airway patency and nasal aesthetics. Closed reduction, using topical 4% cocaine and locally injected 1% lidocaine, should be attempted within 1 week of injury. In the presence of marked nasal swelling, it is best to wait several days for the edema to subside before undertaking reduction. Persistent functional or cosmetic defects may be repaired by delayed reconstructive nasal surgery.

Intranasal examination should be performed in all cases to rule out septal hematoma, which appears as a widening of the anterior septum, visible just posterior to the columella. The septal cartilage receives its only nutrition from its closely adherent mucoperichondrium. An untreated subperichondrial hematoma will result in loss of the nasal cartilage with resultant saddle nose deformity. Septal hematomas may become infected, with *S aureus* the predominant organism, and should be drained with an incision in the inferior mucoperichondrium on both sides. Antibiotics should be given and the drained fluid sent for culture.

Benign Nasal Tumors

Nasal Polyps

Nasal polyps are pale, edematous, mucosally covered masses commonly seen in patients with allergic rhinitis, but compelling evidence argues against a purely allergic pathogenesis. They may result in chronic nasal obstruction and a diminished sense of smell. In patients with nasal polyps and a history of asthma, aspirin should be avoided as it may precipitate a severe episode of bronchospasm, known as triad asthma (Samter triad). Such patients may have an immunologic salicylate sensitivity. The presence of polyps in children should suggest the possibility of cystic fibrosis.

Initial treatment with topical nasal corticosteroids (see Allergic Rhinitis section for specific drugs) for 1–3 months is usually successful for small polyps and may reduce the need for operation. A short course of oral corticosteroids (eg, prednisone, 6-day course using 21 5-mg tablets: 30 mg on day 1 and tapering by 5 mg each day) may also be of benefit. When polyps are massive or medical management is unsuccessful, polyps may be removed surgically. In healthy persons, this is a minor outpatient procedure. In recurrent cases or when surgery itself is associated with increased risk (such as in patients with asthma), a more complete procedure, such as ethmoidectomy, may be advisable. In recurrent polyposis, it may be necessary to remove polyps from the ethmoid, sphenoid, and maxillary sinuses to provide longer-lasting relief. Intranasal corticosteroid should be continued following polyp removal to prevent recurrence, and the clinician should consider allergen testing to determine the offending allergen and avoidance measures.

Inverted Papilloma

Inverted papillomas are benign tumors caused by human papillomavirus (HPV) that usually arise on the lateral nasal wall. They present with unilateral nasal obstruction and occasionally hemorrhage. They are often easily seen on anterior rhinoscopy as cauliflower-like growths in or around the middle meatus. Because SCC is seen in about 10% of inverted or schneiderian papillomas, complete excision is strongly recommended. This usually requires a medial maxillectomy, but in selected cases an endoscopic approach may be possible. Because recurrence rates for inverted papilloma are reported to be as high as 20%, subsequent clinical and radiologic follow-up is imperative. All excised tissue (not just a portion) should be carefully reviewed by the pathologist to be sure no carcinoma is present.

Melroy CT et al. Benign sinonasal neoplasms: a focus on inverting papilloma. Otolaryngol Clin North Am. 2006 Jun;39(3):601–17. [PMID: 16757234]

Juvenile Angiofibroma

These highly vascular tumors arise in the nasopharynx, typically in adolescent males. Initially, they cause nasal obstruction and hemorrhage. Any adolescent male with recurrent epistaxis should be evaluated for an angiofibroma. The clinician should take great care when considering a biopsy because these masses can bleed profusely. Although benign, these tumors expand locally from the sphenopalatine foramen to the pterygopalatine fossa at the pterygoid canal and extend to the pterygoid base, the greater wing of the sphenoid, the nasal cavity, and the paranasal sinuses. They may involve the skull base, usually extradurally, and extend into the superior clivus. Treatment consists of preoperative embolization followed by surgical excision via an approach appropriate for the tumor extent. Small angiofibromas that do not involve the infratemporal fossa may be resected endoscopically. Extensive ones may require skull base approaches. Recurrences are not uncommon and should be resected if possible. Unresectable recurrences that do not appear to grow significantly may be followed radiologically with serial MR scans in expectation of possible eventual involution stabilization or involution of tumor. Low-dose (30 Gy) irradiation may be helpful in nonresectable, continually growing tumors.

Malignant Nasopharyngeal & Paranasal Sinus Tumors

Though rare, malignant tumors of the nose, nasopharynx, and paranasal sinuses are quite problematic as they tend to remain asymptomatic until late in their course. Although the prognosis is poor for advanced tumors, the results of treating resectable tumors of paranasal sinus origin have improved with the wider use of skull base resections and intensity-modulated radiation therapy. Cure rates are often 45–60%. Early symptoms are nonspecific, mimicking those of rhinitis or sinusitis.

Unilateral nasal obstruction, otitis media, and discharge are common, with pain and recurrent hemorrhage often clues to the diagnosis of cancer. Any adult with persistent unilateral nasal symptoms or new otitis media should be thoroughly evaluated by a specialist. A high index of suspicion remains a key to the earlier diagnosis of these tumors. Patients often present with advanced symptoms such as proptosis, expansion of a cheek, or ill-fitting maxillary dentures. Malar hypesthesia, due to involvement of the infraorbital nerve, is common in maxillary sinus tumors. Biopsy is necessary for definitive diagnosis, and MRI is the best imaging study to delineate the extent of disease and plan appropriate surgery and radiation.

SCC is the most common cancer found. It is especially common in the nasopharynx, where it obstructs the eustachian tube and results in serous otitis media. Nasopharyngeal carcinoma (poorly differentiated SCC, nonkeratinizing SCC, or lymphoepithelioma) is usually associated with elevated IgA antibody to the viral capsid antigen of the Epstein-Barr virus (EBV). It is particularly common in patients of southern Chinese descent. Adenocarcinomas, mucosal melanomas, sarcomas, and non-Hodgkin lymphomas are less commonly encountered neoplasms of this area.

Treatment depends on the tumor type and the extent of disease. Nasopharyngeal carcinoma at this time is best treated by concomitant radiation and cisplatin followed by adjuvant chemotherapy with cisplatin and fluorouracil—this protocol significantly decreases local, nodal, and distant failures and increased progression-free and overall survival. Locally recurrent nasopharyngeal carcinoma may in selected cases be treated with repeat irradiation protocols or surgery with moderate success and a high degree of concern about local wound healing. Other SSCs are best treated—when resectable—with a combination of surgery and irradiation. Numerous protocols investigating the role of chemotherapy are under evaluation. Cranial base surgery appears to be an effective modality in improving the overall prognosis in paranasal sinus malignancies eroding the ethmoid roof.

Sinonasal Inflammatory Disease (Wegener Granulomatosis & Sarcoidosis)

The nose and paranasal sinuses are involved in over 90% of cases of Wegener granulomatosis. It is often not realized that involvement at these sites is more common than involvement of lungs or kidneys. Examination shows bloodstained crusts and friable mucosa. Biopsy, when positive, shows necrotizing granulomas and vasculitis. Other recognized sites of Wegener granulomatosis in the head and neck include the subglottis and the middle ear.

Sarcoidosis also commonly involves the paranasal sinuses and is clinically similar to other chronic sinonasal inflammatory processes. Sinonasal symptoms, including rhinorrhea, nasal obstruction, and hyposmia or anosmia may precede diagnosis of sarcoidosis in other organ systems. Clinically, the turbinates appear engorged with small white granulomas. Biopsy shows classic noncaseating granulomas. Notably, patients with sinonasal involvement generally have more trouble managing sarcoidosis in other organ systems.

Polymorphic reticulosis (midline malignant reticulosis, idiopathic midline destructive disease, lethal midline granuloma), as the multitude of apt descriptive terms suggest, is not well understood but appears to be a nasal T-cell or NK cell lymphoma. In contrast to Wegener granulomatosis, involvement is limited to the mid face, and there may be extensive bone destruction. Many destructive lesions of the mucosa and nasal structures labeled as polymorphic reticulosis are in fact non-Hodgkin lymphoma of either NK cell or T cell origin. Immunophenotyping, especially for CD56 expression, is essential in the histologic evaluation. Even when apparently localized, these lymphomas have a poor prognosis, with progression and death within a year the rule.

For treatment of Wegener granulomatosis, see Chapter 20: Musculoskeletal & Immunologic Disorders.

Leukoplakia, Erythroplakia, Oral Lichen Planus, & Oral

Cancer

Essentials of Diagnosis

- **Leukoplakia—**A white lesion that, unlike oral candidiasis, cannot be removed by rubbing the mucosal surface.
- **Erythroplakia**—Similar to leukoplakia except that it has a definite erythematous component.
- **Oral Lichen Planus**—Most commonly presents as lacy leukoplakia but may be erosive; definitive diagnosis requires biopsy.
- **Oral Cancer**—Early lesions appear as leukoplakia or erythroplakia; more advanced lesions will be larger, with invasion into tongue such that a mass lesion is palpable.
- Ulceration may be present.

Leukoplakic regions range from small to several centimeters in diameter (Plate 59). Histologically, they are often hyperkeratoses occurring in response to chronic irritation (eg, from dentures, tobacco, lichen planus); about 2–6%, however, represent either dysplasia or early invasive SCC. Distinguishing between **erythroplakia** and **leukoplakia** is important because about 90% of cases of erythroplakia are either dysplasia or carcinoma. **SCC** accounts for 90% of oral cancer. Alcohol and tobacco use are the major epidemiologic risk factors.

Plate 59.

Leukoplakia with moderate dysplasia on the lateral border of the tongue. (Courtesy of Ellen Eisenberg, DMD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

The differential diagnosis may include oral candidiasis, necrotizing sialometaplasia, pseudoepitheliomatous hyperplasia, median rhomboid glossitis, and vesiculoerosive inflammatory disease such as erosive lichen planus. This should not be confused with the brown-black gingival melanin pigmentation—diffuse or speckled—common in nonwhites, blue-black embedded fragments of dental amalgam, or other systemic disorders associated with general pigmentation (neurofibromatosis, familial polyposis, Addison disease). Intraoral melanoma is extremely rare.

Any area of **erythroplakia**, enlarging area of **leukoplakia**, or a lesion that has submucosal depth on palpation should have an incisional biopsy or an exfoliative cytologic examination. Ulcerative lesions are particularly suspicious and worrisome. Specialty referral should be sought early both for diagnosis and treatment. A systematic intraoral examination—including the lateral tongue, floor of the mouth, gingiva, buccal area, palate, and tonsillar fossae—and palpation of the neck for enlarged lymph nodes should be part of any general physical examination, especially in patients over the age of 45 who smoke tobacco or drink immoderately. Indirect or fiberoptic examination of the nasopharynx, oropharynx, hypopharynx, and larynx by an otolaryngologist, head and neck surgeon, or radiation oncologist should also be considered for such patients when there is unexplained or persistent throat or ear pain, oral or nasal bleeding, or oral erythroplakia. Fine-needle aspiration (FNA) biopsy may expedite the diagnosis if an enlarged lymph node is found. To date, there are no approved therapies for reversing or stabilizing leukoplakia or erythroplakia.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Oral lichen planus is a relatively common (0.5–2% of the population) chronic inflammatory autoimmune disease that may be difficult to diagnose clinically because of its numerous distinct phenotypic subtypes. For example, the reticular pattern may mimic candidiasis or hyperkeratosis, while the erosive pattern may mimic SCC. Management begins with distinguishing it from other oral lesions. Exfoliative cytology or a small incisional or excisional biopsy is indicated, especially if SCC is suspected. Therapy is aimed at managing pain and discomfort. Corticosteroids have been used widely both locally and systemically. Cyclosporines and retinoids have also been used. Many think there is a low rate (1%) of SCC arising within lichen planus (in addition to the possibility of clinical misdiagnosis).

Hairy leukoplakia occurs on the lateral border of the tongue and is a common early finding in HIV infection (see Chapter 31: HIV Infection & AIDS). It often develops quickly and appears as slightly raised leukoplakic areas with a corrugated or "hairy" surface (Plate 60). Clinical response following administration of zidovudine or acyclovir has been reported, and treatment is under active investigation.

Plate 60.

Oral hairy leukoplakia on the side of the tongue in AIDS. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

Early detection of SCC is the key to successful management (Plate 61). Lesions less than 4 mm in depth have a low propensity to metastasize. Most patients in whom the tumor is detected before it is 2 cm in diameter are cured by local resection. Radiation is an alternative but not generally used as first-line therapy for small lesions. Large tumors are usually treated with a combination of resection, neck dissection, and external beam radiation. Reconstruction, if required, is done at the time of resection and can involve the use of myocutaneous flaps or vascularized free flaps with or without bone.

Plate 61.

Squamous cell carcinoma of the palate. (Courtesy of Frank Miller, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

A number of clinical trials have suggested a role for beta-carotene, cyclooxygenase (COX)-2 inhibitors, vitamin E, and retinoids in producing regression of leukoplakia and reducing the incidence of recurrent SCCs. Retinoids suppress head and neck and lung carcinogenesis in animal models and inhibit carcinogenesis in individuals with premalignant lesions. They also seem to reduce the incidence of second primary cancers in head and neck and lung cancer patients previously treated for a primary.

Candidiasis

Clinical Findings

Symptoms and Signs

Oral candidiasis (thrush) is usually painful and looks like creamy-white curd-like patches overlying erythematous mucosa (see Plate 28). Because these white areas are easily rubbed off (eg, by a tongue depressor)—unlike leukoplakia or lichen planus—only the underlying irregular erythema may be seen. Oral candidiasis is commonly encountered among the following patients: (1) those who wear dentures, (2) those who are debilitated, (3) those with diabetes, (4) those with anemia, (5) those undergoing chemotherapy or local irradiation, and (6) those receiving corticosteroids or broad-spectrum antibiotics. Angular cheilitis is another manifestation of candidiasis, although it is also seen in nutritional deficiencies (Plate 62).

Plate 28.

Plate 62.

Severe angular cheilitis in HIV-positive man with oral thrush. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

Diagnostic Studies

The diagnosis is made clinically. A wet preparation using potassium hydroxide will reveal spores and may show nonseptate mycelia. Biopsy will show intraepithelial pseudomycelia of *Candida albicans.*

Candidiasis is often the first manifestation of HIV infection, and HIV testing should be considered in patients with no known predisposing cause for *Candida* overgrowth (see also Chapter 31: HIV Infection & AIDS). The US Department of Health Services Clinical Practice Guideline for Evaluation and Management of Early HIV Infection recommends examination of the oral mucosa with each clinician visit as well as at a dental examination every 6 months.

Treatment

Effective antifungal therapy may be achieved with any of the following: fluconazole (100 mg/d for 7–14 days), ketoconazole (200–400 mg with breakfast [requires acidic gastric environment for absorption] for 7–14 days), clotrimazole troches (10 mg dissolved orally five times daily), or nystatin vaginal troches (100,000 units dissolved orally five times daily) or mouth rinses (500,000 units [5 mL of 100,000 units/mL] held in the mouth before swallowing three times daily). Shorter-duration therapy using fluconazole has proved effective. In patients with HIV infection, however, longer courses may be needed, and oral itraconazole (200 mg/d) may be indicated in fluconazole-refractory cases. Many of the *Candida* species in these patients are resistant to first-line azoles and may require newer drugs, such as voriconazole. In addition, 0.12% chlorhexidine or half-strength hydrogen peroxide mouth rinses may provide local relief. Nystatin powder (100,000 units/g) applied to dentures three or four times daily for several weeks may help denture wearers.

Glossitis, Glossodynia, Dysgeusia, & Burning Mouth Syndrome

Inflammation of the tongue with loss of filiform papillae leads to a red, smooth-surfaced tongue (glossitis). Rarely painful, it may be secondary to nutritional deficiencies (eg, niacin, riboflavin, iron, or vitamin E), drug reactions, dehydration, irritants, foods and liquids, and possibly autoimmune reactions or psoriasis. If the primary cause cannot be identified and corrected, empiric nutritional replacement therapy may be of value.

Glossodynia is burning and pain of the tongue, which may occur with or without glossitis. In the absence of any clinical findings, it has been termed "the burning mouth syndrome." Glossodynia with glossitis has been associated with diabetes mellitus, drugs (eg, diuretics), tobacco, xerostomia, and candidiasis as well as the listed causes of glossitis. Periodontal disease is not apt to be a factor. The burning mouth syndrome typically has no identifiable associated risk factors and seems to be most common in postmenopausal women. Treating possible underlying causes, changing long-term medications to alternative ones, and smoking cessation may resolve symptoms of glossitis. Both glossodynia and the burning mouth syndrome are benign, and reassurance that there is no infection or tumor is likely to be appreciated. Effective treatments for the burning mouth syndrome include alpha-lipoic acid and clonazepam. Clonazepam is most effective as a rapid dissolving tablet placed on the tongue in doses from 0.25 mg to 0.5 mg every 8–12 hours. Behavioral therapy has also been shown to be effective. Unilateral symptoms, symptoms that cannot be related to a specific medication, and symptoms and signs involving regions supplied by other cranial nerves all may suggest neuropathology, and imaging of the brain, brainstem, and skull base with MRI should be considered.

Intraoral Ulcerative Lesions

Necrotizing Ulcerative Gingivitis (Trench Mouth, Vincent Infection)

Necrotizing ulcerative gingivitis, often caused by an infection of both spirochetes and fusiform bacilli, is common in young adults under stress (classically at examination time). Underlying systemic diseases may also predispose to this disorder. Clinically, there is painful acute gingival inflammation and necrosis, often with bleeding, halitosis, fever, and cervical lymphadenopathy (see photograph). Warm half-strength peroxide rinses and oral penicillin (250 mg three times daily for 10 days) may help. Dental gingival curettage may prove necessary.

Fig.

Acute necrotizing ulcerative gingivitis. Gingival lesions can be seen on the medial aspect of the patient's left upper rear molars.

Necrotizing ulcerative periodontitis is discussed later in this chapter in the section on AIDS.

Aphthous Ulcer (Canker Sore, Ulcerative Stomatitis)

Aphthous ulcers are very common and easy to recognize. Their cause remains uncertain, although an association with human herpesvirus 6 has been suggested. Found on nonkeratinized mucosa (eg, buccal and labial mucosa and not attached gingiva or palate), they may be single or multiple, are usually recurrent, and appear as painful small (usually 1–2 mm, but sometimes 1–2 cm) round ulcerations with yellow-gray fibrinoid centers surrounded by red halos (Plate 63). The painful stage lasts 7–10 days; healing is completed in 1–3 weeks.

Plate 63.

Aphthous stomatitis. (Courtesy of Ellen Eisenberg, DMD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

Treatment is nonspecific. Topical corticosteroids (triamcinolone acetonide, 0.1%, or fluocinonide ointment, 0.05%) in an adhesive base (Orabase Plain) do appear to provide symptomatic relief. Other topical therapies shown to be effective in controlled studies include diclofenac 3% in hyaluronan 2.5%, doxymycine-cyanoacrylate, mouthwashes containing the enzymes amyloglucosidase and glucose oxidase, and amlexanox 5% oral paste. A 1-week tapering course of prednisone (40–60 mg/d) has also been used successfully. Cimetidine maintenance therapy may be useful in patients with recurrent aphthous ulcers. Thalidomide has been used selectively in recurrent aphthous ulcerations in HIV-positive patients.

Large or persistent areas of ulcerative stomatitis may be secondary to erythema multiforme or drug allergies, acute herpes simplex, pemphigus, pemphigoid, epidermolysis bullosa acquisita, bullous lichen planus, Behçet disease, or inflammatory bowel disease. SCC may occasionally present in this fashion. When the diagnosis is not clear, incisional biopsy is indicated.

Scully C et al. Oral mucosal disease: recurrent aphthous stomatitis. Br J Oral Maxillofac Surg. 2008 Apr;46(3):198–206. [PMID: 17850936]

Herpetic Stomatitis

Herpetic gingivostomatitis is common, mild, and short-lived and requires no intervention in most adults. In immunocompromised persons, however, reactivation of herpes simplex virus infection is frequent and may be severe. Clinically, there is initial burning, followed by typical small vesicles that rupture and form scabs. Acyclovir (200–800 mg five times daily for 7–14 days) may shorten the course and reduce postherpetic pain. Differential diagnosis includes aphthous stomatitis (see above), erythema multiforme, syphilitic chancre, and carcinoma. Coxsackievirus-caused lesions (grayish white tonsillar and palatal ulcers of herpangina or buccal and lip ulcers in hand-foot-and-mouth disease) are seen more commonly in children under age 6.

Pharyngitis & Tonsillitis

Essentials of Diagnosis

- Sore throat.
- Fever.
- Anterior cervical adenopathy.
- Tonsillar exudate.
- Focus is to treat group A -hemolytic streptococcus infection to prevent rheumatic sequelae.

General Considerations

Pharyngitis and tonsillitis account for over 10% of all office visits to primary care clinicians and 50% of outpatient antibiotic use. The most appropriate management continues to be debated because some of the issues are deceptively complex, but consensus has increased in recent years. The main concern is determining who is likely to have a group A -hemolytic streptococcal infection (GABHS), as this can lead to subsequent complications such as rheumatic fever and glomerular nephritis. A second public health policy concern is reducing the extraordinary cost (both in dollars and in the development of antibiotic-resistant *S pneumoniae*) in the United States associated with unnecessary antibiotic use. Questions now being asked: Is there still a role for culturing a sore throat, or have the rapid antigen tests supplanted this procedure under most circumstances? Are clinical criteria alone a sufficient basis for decisions about which patients should be given antibiotics? Should any patient receive any antibiotic other than penicillin (or erythromycin if penicillin-allergic)? For how long should treatment be continued? Numerous well-done studies in the past few years as well as increasing experience with rapid laboratory tests for detection of streptococci (eliminating the delay caused by culturing) appear to make a consensus approach more possible.

Clinical Findings

The clinical features most suggestive of group A -hemolytic streptococcal pharyngitis include fever over 38 °C, tender anterior cervical adenopathy, lack of a cough, and a pharyngotonsillar exudate (Plates 64 and 65). These four features (the Centor criteria), when present, strongly suggest GABHS, and some would treat regardless of laboratory results. When three of the four are present, laboratory sensitivity of rapid antigen testing exceeds 90%. When only one criterion is present, GABHS is unlikely. Sore throat may be severe, with odynophagia, tender adenopathy, and a scarlatiniform rash. An elevated white count and left shift are also possible. Hoarseness, cough, and coryza are not suggestive of this disease.

Marked lymphadenopathy and a shaggy white-purple tonsillar exudate, often extending into the nasopharynx, suggest mononucleosis, especially if present in a young adult. Recently, the lymphocyte-white blood cell count ratio has been reported to efficiently and specifically differentiate tonsillitis from infectious mononucleosis. With about 90% sensitivity, lymphocyte ratios of greater than 35% suggest EBV infection. Hepatosplenomegaly and a positive heterophil agglutination test or elevated anti-EBV titer are corroborative. However, about one-third of patients with infectious mononucleosis have secondary streptococcal tonsillitis, requiring treatment. Ampicillin should routinely be avoided if mononucleosis is suspected because it induces a rash that might be misinterpreted by the patient as a penicillin allergy. Diphtheria (extremely rare but described in the alcoholic population) presents with low-grade fever and an ill patient with a gray tonsillar pseudomembrane.

The most common pathogens other than group A -hemolytic streptococci in the differential diagnosis of "sore throat" are viruses, *Neisseria gonorrhoeae*, *Mycoplasma*, and *Chlamydia trachomatis*. Rhinorrhea and lack of exudate would suggest a virus, but in practice it is not possible to confidently distinguish viral upper respiratory infection from GABHS on clinical grounds alone. Infections with *Corynebacterium diphtheriae*, anaerobic streptococci, and *Corynebacterium haemolyticum* (which responds better to erythromycin than penicillin) may also mimic pharyngitis due to group A -hemolytic streptococci.

Treatment

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Given the availability of many well-documented studies in recent years, one would think that a consensus might develop as to the most appropriate way to treat a sore throat. The Infectious Diseases Society of America recommends laboratory confirmation of the clinical diagnosis by means of either throat culture or a rapid antigen detection test. The American College of Physicians–American Society of Internal Medicine (ACP-ASIM), in collaboration with the Centers for Disease Control and Prevention, advocates use of a clinical algorithm alone—in lieu of microbiologic testing—for confirmation of the diagnosis in adults for whom the suspicion of streptococcal infection is high. Others examine the assumptions of the ACP-ASIM guideline for using a clinical algorithm alone and question whether those recommendations will achieve the stated objective of dramatically decreasing excess antibiotic use. Convincing clinical trials as well as clinician reminders and patient-based interventions may be needed before clinicians are likely to abandon long-held teachings (even though different clinicians appear to have been taught different strategies) regarding diagnosis and management of group A streptococcal pharyngitis. A Cochrane review concluded that multifaceted interventions where educational interventions occur on many levels were the only interventions whose effects were of sufficient magnitude to potentially reduce the incidence of antibiotic-resistant bacteria.

Thirty years ago, a single injection of benzathine penicillin or procaine penicillin was standard antibiotic treatment. This remains effective, but the injections are painful. If compliance is an issue, it may be the best choice. Oral treatment is also effective. Antibiotic choice aims to reduce the already low (10–20%) incidence of treatment failures (positive culture after treatment despite symptomatic resolution) and recurrences. A review of recent controlled studies suggests that penicillin V potassium (250 mg orally three times daily or 500 mg twice daily for 10 days) or cefuroxime axetil (250 mg orally twice daily for 5–10 days) are both effective. The efficacy of a 5-day regimen of penicillin V appears to be similar to that of a 10-day course, with a 94% clinical response rate and an 84% streptococcal eradication rate. Erythromycin (active against *Mycoplasma* and *Chlamydia*) is a reasonable alternative to penicillin in allergic patients. Cephalosporins are somewhat more effective than penicillin in producing bacteriologic cures; 5-day administration has been successful for cefpodoxime and cefuroxime. The macrolide antibiotics have also been reported to be successful in shorter-duration regimens.

Azithromycin (500 mg once daily), because of its long half-life, need be taken for only 3 days.

Adequate antibiotic treatment usually avoids the streptococcal complications of scarlet fever, glomerulonephritis, rheumatic myocarditis, and local abscess formation.

Antibiotics for treatment failures are also somewhat controversial. Surprisingly, penicillin-tolerant strains are not isolated more frequently in those who fail treatment than in those treated successfully with penicillin. The reasons for failure appear to be complex, and a second course of treatment with the same drug is not unreasonable. Alternatives to penicillin include cefuroxime and other cephalosporins, dicloxacillin (which is -lactamase–resistant), and amoxicillin with clavulanate. When there is a history of penicillin allergy, alternatives should be used, such as erythromycin. Erythromycin resistance—with failure rates of about 25%—is an increasing problem in many areas. In cases of severe penicillin allergy, cephalosporins should be avoided as the cross-reaction is common (8% or more).

Ancillary treatment of pharyngitis includes analgesics and anti-inflammatory agents, such as aspirin or acetaminophen. Some patients find that salt water gargling is soothing. In severe cases, anesthetic gargles and lozenges (eg, benzocaine) may provide additional symptomatic relief. Occasionally, odynophagia is so intense that hospitalization for intravenous hydration and antibiotics is necessary. (See Chapter 33: Bacterial & Chlamydial Infections.)

Peritonsillar Abscess & Cellulitis

When infection penetrates the tonsillar capsule and involves the surrounding tissues, peritonsillar cellulitis results. Peritonsillar abscess and cellulitis present with severe sore throat, odynophagia, trismus, medial deviation of the soft palate and peritonsillar fold, and an abnormal muffled ("hot potato") voice. Following therapy, peritonsillar cellulitis usually either resolves over several days or evolves into peritonsillar abscess, also known as quinsy (see illustration). The existence of an abscess may be confirmed by aspirating pus from the peritonsillar fold just superior and medial to the upper pole of the tonsil (see illustration). A No. 19 or No. 21 needle should be passed medial to the molar and no deeper than 1 cm, because the internal carotid artery may lie more medially than its usual location and pass posterior and deep to the tonsillar fossa. There is controversy regarding the three ways to treat a peritonsillar abscess: needle aspiration, incision and drainage, or tonsillectomy. Some clinicians incise and drain the area and continue with parenteral antibiotics, whereas others aspirate only and monitor as an outpatient. To drain the abscess and avoid recurrence, it may be appropriate to consider immediate tonsillectomy (quinsy tonsillectomy). About 10% of patients with peritonsillar abscess exhibit relative indications for tonsillectomy. All three approaches are effective and have support in the literature. Regardless of the method used, one must be sure the abscess is adequately treated, since complications such as extension to the retropharyngeal, deep neck, and posterior mediastinal spaces are possible. Bacteria may also be aspirated into the lungs, resulting in pneumonia. While there is controversy about whether a single abscess is sufficient indication for tonsillectomy, most would agree that patients with recurrent abscesses should have a tonsillectomy.

needle aspiration versus incision and drainage versus tonsillectomy. Am J Ther. 2005 Jul–Aug;12(4):344–50. [PMID: 16041198]

Tonsillectomy

Despite the frequency with which tonsillectomy is performed, the indications for the procedure remain controversial. Most clinicians would agree that airway obstruction causing sleep apnea or cor pulmonale is an absolute indication for tonsillectomy. Similarly, persistent marked tonsillar asymmetry should prompt an excisional biopsy to rule out lymphoma. Relative indications include recurrent streptococcal tonsillitis, causing considerable loss of time from school or work, recurrent peritonsillar abscess, and chronic tonsillitis.

Tonsillectomy is not an entirely benign procedure. The pros and cons of tonsillectomy need to be discussed with each prospective patient. Postoperative bleeding occurs in 2–4% of cases and on rare occasions can lead to laryngospasm and airway obstruction. Pain may be considerable, especially in the adult. Protracted emesis or fever may also occasionally occur. Secondary bleeding 5–8 days postoperatively is far more common than bleeding in the first 24 hours. There is increasing economic pressure for these procedures to be done as outpatient surgery. At present it seems clear that outpatient tonsillectomy is usually safe when followed by a 6-hour period of uneventful observation, but individual circumstances may mandate hospitalization.

Although reports in the 1970s suggested an association of tonsillectomy with Hodgkin disease, careful review of this literature reveals no conclusively causative association.

Deep Neck Infections

Deep neck abscesses usually present with marked neck pain and swelling in a toxic febrile patient. They are emergencies because they may rapidly compromise the airway. They may also spread to the mediastinum or cause septicemia. Most commonly, they originate from odontogenic infections. Other causes include suppurative lymphadenitis, direct spread of pharyngeal infection, penetrating trauma, pharyngoesophageal foreign bodies, cervical osteomyelitis, and intravenous injection of the internal jugular vein, especially in drug abusers. Recurrent deep neck infection may suggest an underlying congenital lesion such as a branchial cleft cyst. Suppurative lymphadenopathy in middle-age persons who smoke and drink alcohol regularly should be considered a manifestation of malignancy (typically metastatic SCC) until proven otherwise.

Fundamentals of treatment include securing the airway, intravenous antibiotics, and incision and drainage. In highly selected patients without airway compromise, needle aspiration and catheter drainage or even conservative management without antibiotics alone has been reported to be successful in uniloculated abscesses. The airway may be secured, when indicated, either by intubation or tracheotomy. Tracheotomy is preferable in the patients with substantial pharyngeal edema, since attempts at intubation may precipitate acute airway obstruction. Bleeding in association with a deep neck abscess suggests the possibility of carotid artery or internal jugular vein involvement and requires prompt neck exploration both for drainage of pus and for vascular control.

Contrast-enhanced CT usually augments the clinical examination in defining the extent of the infection. It often will distinguish inflammation (requiring antibiotics) from abscess (requiring drainage) and define for the surgeon the extent of an abscess. CT with MRI may also identify thrombophlebitis of the internal jugular vein secondary to oropharyngeal inflammation. This condition, known as Lemierre syndrome, may be associated with septic emboli and requires prompt institution of antibiotics appropriate for *Fusobacterium necrophorum* as well as the more usual upper airway pathogens. The presence of pulmonary infiltrates (or septic arthritis) in the setting of a neck abscess should lead one to suspect Lemierre syndrome.

Ludwig angina is the most commonly encountered neck space infection. It is a cellulitis of the sublingual and submaxillary spaces, often arising from infection of the mandible. Clinically, there is edema and erythema of the upper neck under the chin and often of the floor of the mouth. The tongue may be displaced upward and backward by the posterior spread of cellulitis. This may lead to occlusion of the airway and necessitate tracheotomy. Microbiologic isolates include streptococci, staphylococci, *Bacteroides*, and *Fusobacterium*. Usual doses of penicillin plus metronidazole, ampicillin-sulbactam, clindamycin, or selective cephalosporins are good initial choices. Culture and sensitivity data will then refine the choice. Dental consultation is advisable. External drainage via bilateral submental incisions is required if the airway is threatened or when medical therapy has not reversed the process.

Acute Inflammatory Salivary Gland Disorders

Sialadenitis

Acute bacterial sialadenitis in the adult most commonly affects either the parotid or submandibular gland. It typically presents with acute swelling of the gland, increased pain and swelling with meals, and tenderness and erythema of the duct opening. Pus often can be massaged from the duct. Sialadenitis often occurs in the setting of dehydration or in association with chronic illness. Underlying Sjögren syndrome may contribute. Ductal obstruction, often by an inspissated mucous plug, is followed by salivary stasis and secondary infection. The most common organism recovered from purulent draining saliva is *S aureus*. Treatment consists of intravenous antibiotics such as nafcillin (1 g intravenously every 4–6 hours) and measures to increase salivary flow, including hydration, warm compresses, sialagogues (eg, lemon drops), and massage of the gland. Usually one can switch to an oral agent based on clinical and microbiologic improvement to complete a 10-day course. Failure of the process to resolve on this regimen suggests abscess formation, ductal stricture, stone, or tumor causing obstruction. Ultrasound or CT scan may be helpful in establishing the diagnosis. In the setting of acute illness, a severe and potentially life-threatening form of sialadenitis, sometimes called "suppurative sialadenitis" may develop. The causative organism is usually *S aureus*, but often no pus will drain from Stensen papilla. These patients often do not respond to rehydration and intravenous antibiotics and thus may require operative incision and drainage to resolve the infection.

Sialolithiasis

Calculus formation is more common in Wharton duct (draining the submandibular glands) than in Stensen duct (draining the parotid glands). Clinically, a patient may note postprandial pain and local swelling, often with a history of recurrent acute sialadenitis. Stones in Wharton duct are usually large and radiopaque, whereas those in Stensen duct are usually radiolucent and smaller. Those very close to the orifice of Wharton duct may be palpated manually in the anterior floor of the mouth and removed intraorally by dilating or incising the distal duct. The duct proximal to the stone must be temporarily clamped (using, for instance, a single throw of a suture) to keep manipulation of the stone from pushing it back toward the submandibular gland. Those more than 1.5–2 cm from the duct are too close to the lingual nerve to be removed safely in this manner. Similarly, dilation of Stensen duct, located on the buccal surface opposite the second maxillary molar, may relieve distal stricture or allow a small stone to pass. Extracorporeal shock-wave lithotripsy and fluoroscopically guided basket retrieval have been used successfully, but are being replaced by sialoendoscopy for the management of chronic sialolithiasis. Repeated episodes of sialadenitis are usually associated with stricture and chronic infection. If the obstruction cannot be safely removed or dilated, excision of the gland may be necessary to relieve recurrent symptoms.

Chronic Inflammatory & Infiltrative Disorders of the Salivary Glands

Numerous infiltrative disorders may cause unilateral or bilateral parotid gland enlargement. Sjögren disease and sarcoidosis are examples of lymphoepithelial and granulomatous diseases that may affect the salivary glands. Metabolic disorders, including alcoholism, diabetes mellitus, and vitamin deficiencies, may also cause diffuse enlargement. Several drugs have been associated with parotid enlargement, including thioureas, iodine, and drugs with cholinergic effects (eg, phenothiazines), which stimulate salivary flow and cause more viscous saliva.

Salomonsson S et al. Minor salivary gland immunohistology in the diagnosis of primary Sjögren's syndrome. J Oral Pathol Med. 5009 Mar;38(2):282–8. [PMID: 18793250]

Salivary Gland Tumors

Approximately 80% of salivary gland tumors occur in the parotid gland. In adults, about 80% of these are benign. In the submandibular triangle, it is sometimes difficult to distinguish a primary submandibular gland tumor from a metastatic submandibular space node. Only 50–60% of primary submandibular tumors are benign. Tumors of the minor salivary glands are most likely to be malignant, with adenoid cystic carcinoma predominating.

Most parotid tumors present as an asymptomatic mass in the superficial part of the gland. Their presence may have been noted by the patient for months or years. Facial nerve involvement correlates strongly with malignancy. Tumors may extend deep to the plane of the facial nerve or may originate in the parapharyngeal space. In such cases, medial deviation of the soft palate is visible on intraoral examination. MRI and CT scans have largely replaced sialography in defining the extent of tumor.

When the clinician encounters a patient with an otherwise asymptomatic salivary gland mass where tumor is the most likely diagnosis, the choice is whether to simply excise the mass via a parotidectomy with facial nerve dissection or submandibular gland excision or to obtain an FNA biopsy first. Although the accuracy of FNA biopsy for malignancy has been reported to be quite high, results vary among institutions. If a negative FNA biopsy would lead to a decision not to proceed to surgery, then it should be considered. Poor overall health of the patient and the possibility of inflammatory disease as the cause of the mass are situations where FNA biopsy might be helpful. In otherwise straightforward nonrecurrent cases, excision is indicated. In benign and small low-grade malignant tumors, no additional treatment is needed. Postoperative irradiation is indicated for larger and high-grade cancers.

Dysphonia, Hoarseness, & Stridor

The primary symptoms of laryngeal disease are hoarseness and stridor. Hoarseness is caused by an abnormal vibration of the vocal folds. The voice is breathy when too much air passes incompletely apposed vocal folds, as in unilateral vocal fold paralysis or vocal fold mass. The voice is harsh when the vocal folds are stiff and vibrate irregularly, as is the case in laryngitis or malignancy. Heavy, edematous vocal folds produce a rough vocal quality. Stridor (a high-pitched, typically inspiratory, sound) is the result of turbulent airflow from a narrowed glottis. Airway narrowing at or above the vocal folds produces inspiratory stridor. Airway narrowing below the vocal fold level produces either expiratory or biphasic stridor. The timing and rapidity of onset of stridor are critically important in determining the seriousness of the airway problem. All cases of stridor should be evaluated by a specialist and rapid-onset stridor should be evaluated emergently.

Evaluation of an abnormal voice begins with obtaining a history of the circumstances preceding its onset and an examination of the airway.

Any patient with hoarseness that has persisted beyond 2 weeks should be evaluated by an otolaryngologist with laryngoscopy. Especially when the patient has a history of tobacco use, laryngeal cancer or lung cancer (leading to paralysis of a recurrent laryngeal nerve) must be strongly considered. In addition to structural causes of dysphonia, laryngoscopy can help identify functional problems with the voice including vocal fold paralysis, muscle tension dysphonia, and spasmodic dysphonia.

Common Laryngeal Disorders

Epiglottitis

Epiglottitis (or, more correctly, supraglottitis) in adults should be suspected when a patient presents with a rapidly developing sore throat or when odynophagia (pain on swallowing) is out of proportion to apparently minimal oropharyngeal findings on examination (see photograph, x-ray). It is more common in diabetics and may be viral or bacterial in origin. Rarely in the era of *H influenzae* type b vaccine is this bacterium isolated in adults. Unlike in children, indirect laryngoscopy is generally safe and may demonstrate a swollen, erythematous epiglottis (see illustration). Lateral plain radiographs may demonstrate an enlarged epiglottis (the epiglottis "thumb sign"). Initial treatment is hospitalization for intravenous antibiotics—eg, ceftizoxime, 1–2 g intravenously every 8–12 hours; or cefuroxime, 750–1500 mg intravenously every 8 hours; and dexamethasone, usually 4–10 mg as initial bolus, then 4 mg intravenously every 6 hours—and observation of the airway. Corticosteroids may be tapered as symptoms and signs resolve. Similarly, substitution of oral antibiotics may be appropriate to complete a 10-day course. Less than 10% of adults require intubation. Indications for intubation are dyspnea, rapid pace of sore throat (where progression to airway compromise may occur before the effects of corticosteroids and antibiotics), and endolaryngeal abscess noted on CT imaging. If the patient is not intubated, prudence suggests monitoring oxygen saturation with continuous pulse oximetry and initial admission to a monitored unit.

Recurrent Respiratory Papillomatosis

Papillomas are common lesions of the larynx and other sites where ciliated and squamous epithelia meet. Unlike oral papillomas, recurrent respiratory papillomatosis is likely to be symptomatic, with hoarseness that occasionally progresses to stridor over weeks to months. These papillomas are almost always HPV types 6 and 11. The disease is more common in children. Repeated laser vaporizations or cold knife resections via operative laryngoscopy are usually the mainstay of treatment. Severe cases can require treatment as often as every 6 weeks to maintain airway patency. Extension can occur into the trachea and lungs. Tracheotomy should be avoided, if possible, since it introduces an additional squamociliary junction for which papillomas appear to have a tropism. Interferon treatment has been under investigation for over two decades but is only indicated in severe cases with pulmonary involvement. Rarely, cases of malignant transformation have been reported (often in smokers), but recurrent respiratory papillomatosis should generally be thought of as a benign condition. Cidofovir (a cytosine nucleotide analog in use to treat cytomegalovirus retinitis) is also being investigated as intralesional therapy for recurrent respiratory papillomatosis and has had reported success in both adults and children. Because cidofovir causes adenocarcinomas in laboratory animals, its potential for carcinogenesis is being monitored. A quadrivalent recombinant human HPV vaccine (Gardasil) has been approved by the FDA, with HPV type 6 and 11 epitopes conferring immunity in the patient. While not useful as a treatment option for patients with recurrent respiratory papillomatosis, this vaccine offers hope for the eventual eradication of this benign, but terribly morbid, disease.

Chadha NK. Antiviral agents for the treatment of recurrent respiratory papillomatosis: a systematic review of the English-language literature. Otolaryngol Head Neck Surg. 2007 Jun;136(6):863–9. [PMID: 17547971]

Derkay CS et al. Recurrent respiratory papillomatosis. Ann Otol Rhinol Laryngol. 2006 Jan;115(1):1–11. [PMID: 16466093]

Acute Laryngitis

Acute laryngitis is probably the most common cause of hoarseness, which may persist for a week or so after other symptoms of an upper respiratory infection have cleared. The patient should be warned to avoid vigorous use of the voice (singing, shouting) until their voice returns to normal, since persistent use may lead to the formation of traumatic vocal polyps, nodules and cysts. Although thought to be usually viral in origin, both *M catarrhalis* and *H influenzae* may be isolated from the nasopharynx at higher than expected frequencies. Erythromycin may reduce the severity of hoarseness and cough.

Reveiz L et al. Antibiotics for acute laryngitis in adults. Cochrane Database Syst Rev. 2005 Jan 25;(1):CD004783. [PMID: 15674965]

Laryngopharyngeal Reflux

Gastroesophageal reflux into the larynx (laryngopharyngeal reflux) is considered a possible cause of chronic hoarseness when other causes of abnormal vocal fold vibration (such as tumor or nodules) have been excluded by laryngoscopy. Gastroesophageal reflux disease (GERD) has also been suggested as a contributing factor to other symptoms such as throat clearing, throat discomfort, chronic cough, a sensation of postnasal drip, and esophageal spasm; as well as in many cases of posterior laryngitis and some cases of asthma. Since less than half of patients with laryngeal acid exposure have typical symptoms of heartburn and regurgitation, the lack of such symptoms should not be construed as eliminating this cause. Indeed, most patients with symptomatic laryngopharyngeal reflux, as it is now called, do not meet criteria for GERD by pH probe testing and these entities must be considered separately.

Management should initially exclude other causes of dysphonia through laryngoscopy and consultation with an otolaryngologist is advisable. Many clinicians opt for an empiric trial of a proton pump inhibitor as a practical alternative to an initial pH study. If used, the American Academy of Otolaryngology Head and Neck Surgery recommends twice daily therapy with full strength proton pump inhibitor (eg, omeprazole 40 mg orally twice daily, or equivalent) for a minimum of 3 months. Patients may note improvement in symptoms after 3 months, but the changes in the larynx often take 6 months to resolve. If symptoms improve and cessation of therapy leads to symptoms again, then a proton pump inhibitor is resumed at the lowest dose effective for remission, usually daily but at times on a demand basis. Although H_2-receptor antagonists are an alternative to proton pump inhibitors, they are generally both less clinically effective and less cost-effective. Nonresponders should undergo pH testing and manometry. Twenty-four-hour pH monitoring of the pharynx should best document laryngopharyngeal reflux and is advocated by some as the initial management step but it is costly, more difficult, and less available than lower esophageal monitoring alone. Lower esophageal pH monitoring does not correlate well with laryngopharyngeal reflux symptoms and double pH probe (proximal and distal) testing is accepted as the standard of care for evaluation of laryngopharyngeal reflux.

Tumors of the Larynx

Traumatic Lesions of the Vocal Folds

Vocal fold nodules are smooth, paired lesions that form at the junction of the anterior one-third and posterior two-thirds of the vocal folds. They are a common cause of hoarseness resulting from vocal abuse. In adults, they are referred to as "singer's nodules"; in children, "screamer's nodules." Treatment requires modification of voice habits, and referral to a speech therapist is indicated. While nearly all true nodules will resolve with behavior modification, recalcitrant nodules may require surgical excision. Often, additional pathology, such as a polyp or cyst, may be encountered.

Vocal fold polyps are unilateral masses that form within the superficial lamina propria of the vocal fold. They are related to vocal trauma and seem to follow resolution of vocal fold hemorrhage. Small, sessile polyps may resolve with conservative measures, such as voice rest and corticosteroids, but larger polyps are often irreversible and require operative resection.

Vocal fold nodules are smooth, paired lesions that form at the junction of the anterior one-third and posterior two-thirds of the vocal folds. They are a common cause of hoarseness resulting from vocal abuse. In adults, they are referred to as "singer's nodules"; in children, "screamer's nodules." Treatment requires modification of voice habits, and referral to a speech therapist is indicated. While nearly all true nodules will resolve with behavior modification, recalcitrant nodules may require surgical excision. Often, additional pathology, such as a polyp or cyst, may be encountered.

Vocal fold polyps are unilateral masses that form within the superficial lamina propria of the vocal fold. They are related to vocal trauma and seem to follow resolution of vocal fold hemorrhage. Small, sessile polyps may resolve with conservative measures, such as voice rest and corticosteroids, but larger polyps are often irreversible and require operative resection.

Vocal fold cysts are also considered traumatic lesions of the vocal folds and are either true cysts with an epithelial lining or pseudocysts. They typically form from mucus-secreting glands on the inferior aspect of the vocal folds. Cysts may fluctuate in size from week to week and cause a variable degree of hoarseness. They rarely, if ever, resolve completely and may leave behind a sulcus, or vocal fold scar, if they decompress or are marsupialized. Such scarring can be a frustrating cause of permanent dysphonia.

Polypoid corditis is different from vocal fold polyps and may form from loss of elastin fibers and loosening of the intracellular junctions within the lamina propria. This loss allows swelling of the gelatinous matrix of the superficial lamina propria (called Reinke edema). These changes in the vocal folds are strongly associated with smoking, but also with vocal abuse, chemical industrial irritants, and hypothyroidism. While this problem is common in both male and female smokers, women seem more troubled by the characteristic decline in modal pitch caused by the increased mass of the vocal folds. If the habits change or the lesions cause stridor and airway obstruction, surgical resection of the hyperplastic vocal fold mucosa may be indicated to improve the airway and voice.

A common but often unrecognized cause of hoarseness is contact ulcers or granulomas on the vocal processes of the arytenoid cartilages. The cause of these ulcers is disputed, but they are clearly related to trauma and may be related to exposure of the underlying perichondrium. They are common following intubation and generally resolve quite quickly. Chronic ulceration or granuloma formation has been associated with esophageal reflux but is also common in patients with muscle tension dysphonia. Treatment is often multimodal with proton pump inhibitor therapy (omeprazole 40 mg orally twice daily, or equivalent) and voice therapy with special attention to vocal hygiene. Rare cases can be quite stubborn and persistent without adequate therapy.

Laryngeal Leukoplakia

Leukoplakia of the vocal folds is commonly found in association with hoarseness in smokers. Direct laryngoscopy with biopsy is advised in almost all cases. Histologic examination usually demonstrates mild, moderate, or severe dysplasia. In some cases, invasive SCC is present in the initial biopsy specimen. Cessation of smoking may reverse or stabilize mild or moderate dysplasia. A certain percentage of patients—estimated to be less than 5% of those with mild dysplasia and about 35–60% of those with severe dysplasia—will subsequently develop SCC. Treatment options include close follow-up with laryngovideostroboscopy, serial resection, and external beam radiation therapy. Despite their cost and the lack of any evidence for their use in the treatment of leukoplakia, proton pump inhibitors have become the mainstay of treatment for these lesions.

Squamous Cell Carcinoma of the Larynx

Essentials of Diagnosis

- New and persistent (more than 2 weeks duration) hoarseness in a smoker.
- Persistent throat or ear pain, especially with swallowing.
- Neck mass.
- Hemoptysis.
- Stridor or other symptoms of a compromised airway.

Clinical Findings

Symptoms and Signs

SCC of the larynx, the most common malignancy of the larynx, occurs almost exclusively in patients with a history of significant tobacco use, and often with alcohol. SCC is usually seen in men age 50–70 years; about 13,000 new cases are seen in United States each year. A change in voice quality is most often the presenting complaint, although throat or ear pain, hemoptysis, dysphagia, weight loss, and airway compromise may occur. Neck metastases are not common in early glottic (true vocal fold) cancer in which the vocal folds are mobile, but a third of patients in whom there is impaired fold mobility will also have involved lymph nodes at neck dissection. Supraglottic carcinoma (false vocal folds, aryepiglottic folds, epiglottis), on the other hand, often metastasizes to both sides of the neck early in the disease. Complete head and neck examination, including laryngoscopy, by an experienced clinician is mandated for any person with the concerning symptoms listed under Essentials of Diagnosis.

Imaging and Laboratory Studies

Radiologic evaluation by CT or MRI is helpful in assessing tumor extent. Imaging evaluates neck nodes, tumor volume, and cartilage sclerosis or destruction. A chest CT scan is indicated if there are level VI enlarged nodes (around the trachea and the thyroid gland) or IV enlarged nodes (inferior to the cricoid cartilage along the internal jugular vein) or if a chest film is concerning for a second primary lesion or metastases. Laboratory evaluation includes complete blood count and liver function tests. Formal cardiopulmonary evaluation may be indicated, especially if partial laryngeal surgery is being considered. A positron emission tomography (PET) scan or CT-PET scan may be indicated to assess for distant metastases when there appears to be advanced local or regional disease.

Biopsy

Diagnosis is made by biopsy at the time of laryngoscopy. At that time, true fold mobility and arytenoid fixation, as well as surface tumor extent, can be evaluated. Most otolaryngologists recommend flexible esophagoscopy and flexible bronchoscopy at the same time to exclude synchronous primary tumor. Although an FNA biopsy of an enlarged neck node may have already been done, it is generally acceptable to assume radiographically enlarged neck nodes (> 1–1.5 cm) or nodes with necrotic centers are neck metastases. Open biopsies of nodal metastases should be discouraged because they may lead to higher rates of tumor treatment failure.

Tumor Staging

Staging is helpful in discussing laryngeal cancer, but a number of factors that are not included in the TNM staging are also important in deciding treatment recommendations. eTable 8–2.1 outlines (slightly abbreviated) the current American Joint Committee on Cancer (AJCC) tumor staging for the glottis and supraglottis.

eTable 8–2.1. Staging of glottis and supraglottis tumors.

Stage	Glottis	Supraglottis
T1	Limited to true vocal folds	One site, with normal true vocal fold mobility
T2	Extends to supraglottis or subglottis; or impaired true vocal fold mobility	Two sites, with normal true vocal fold mobility
T3	True vocal fold fixation	True vocal fold fixation, or extension to preepiglottic space, medial pyriform sinus, or postcricoid area
T4	Extralaryngeal (eg, invasion of thyroid cartilage or strap muscles)	
N[1]		
N0	No nodes (includes information from physical examination, CT and MRI scans, and positron emission tomography)	
N1	Ipsilateral node < 3 cm	
N2a	Ipsilateral node 3 cm but < 6 cm	
N2b	Ipsilateral multiple nodes, all < 6 cm	

N2c	Bilateral (or contralateral nodes only) < 6 cm
N3	Node(s) 6 cm

[1] N staging is the same for all head and neck squamous cell carcinoma except nasopharyngeal carcinoma.

Treatment

Treatment of laryngeal carcinoma has four goals: cure, preservation of safe effective swallowing, preservation of useful voice, and avoidance of a permanent tracheostoma. For early glottic and supraglottic cancers, radiation therapy is the standard of care since cure rates are greater than 95% and 80%, respectively. That said, radiation therapy carries substantial morbidity and many early tumors (T1 and T2 lesions, without involved nodes) and selected advanced tumors (T3 and T4) may be treated with partial laryngectomy if at least one cricoarytenoid unit can be preserved. Five-year locoregional cure rates exceed 80–90% with surgery, and patient-reported satisfaction is excellent. In supraglottic tumors, even when clinically N0, elective limited neck dissection is indicated following surgical resection because of the high risk of neck node involvement.

For very advanced tumors, cisplatin-based chemoradiation protocols are used. Twenty-five years ago, total laryngectomy was often recommended for such patients. However, the 1994 VA study (with induction cisplatin and 5-fluorouracil followed by irradiation alone in responders) demonstrated that two-thirds of patients could preserve their larynx. Since that study, cisplatin-based chemotherapy concomitant with radiation therapy has been shown to be superior to either irradiation alone or induction chemotherapy followed by radiation. However, chemoradiation is associated with prolonged gastrostomy-dependent dysphagia. This high rate of chemoradiation-associated dysphagia has prompted a reevaluation of the role of extended, but less-than-total, laryngeal surgery for selected advanced laryngeal carcinoma in which at least one cricoarytenoid unit is intact. In addition, overall success in the treatment of larynx cancer has declined in parallel with the increase in organ preservation chemoradiation therapy. Some experts have proposed that this decline is the direct result of the shift in management of advanced laryngeal cancer away from surgery. Organ preservation surgery, should be considered and discussed as an alternative to chemoradiation. Patient comorbidities and patient choice, after thorough discussion, play an important role in the choice between surgery and chemoradiation. The patient and treating clinicians must carefully consider *different* side effects and complications associated with different treatment modalities.

The presence of malignant adenopathy in the neck affects the prognosis greatly. Supraglottic tumors metastasize early and bilaterally to the neck, and this must be included in the treatment plans even when the neck is apparently uninvolved. Glottic tumors in which the true vocal folds are mobile (T1 or T2) have less than a 5% rate of nodal involvement; when a fold is immobile, the rate of ipsilateral nodal involvement climbs to about 30%. An involved neck is treated by surgery or chemoradiation, or both. This decision will depend on the treatment chosen for the larynx and the extent of neck involvement.

Total laryngectomy is largely reserved for patients with far-advanced resectable tumors with extralaryngeal spread or cartilage involvement, for those with persistent tumor following chemoradiation, and for patients with recurrent or second primary tumor following previous radiation therapy. Voice rehabilitation via a primary (or at times secondary) tracheoesophageal puncture produces intelligible and serviceable speech in about 75–85% of patients. Indwelling prostheses that are changed every 3–6 months are a common alternative to patient-inserted prostheses, which need changing more frequently.

Long-term follow-up is critical in head and neck cancer patients. In addition to the 3–4% annual rate of second tumors and monitoring for recurrence, psychosocial aspects of treatment are common. Dysphagia, impaired communication, and altered appearance may result in patient difficulties adapting to the workplace and to social interactions. In addition, smoking cessation and alcohol abatement are common challenges. Nevertheless, about 65% of patients with larynx cancer are cured, most have useful speech, and many resume their prior livelihoods with adaptations.

Vocal Fold Paralysis

Vocal fold paralysis can result from a lesion or damage to either the vagus or recurrent laryngeal nerve and usually results in breathy dysphonia and effortful voicing. Common causes of unilateral recurrent laryngeal nerve involvement include thyroid surgery (and occasionally thyroid cancer), other neck surgery (anterior discectomy and carotid endarterectomy), and mediastinal or apical involvement by lung cancer. Skull base tumors often involve or abut upon lower cranial nerves and may affect the vagus nerve directly, or the vagus nerve may be damaged during surgical management of the lesion. While iatrogenic injury is the most common cause of unilateral vocal fold paralysis, the second most common cause is idiopathic. However, before deciding whether the paralysis is due to iatrogenic injury or is idiopathic, the clinician must exclude other causes, such as malignancy. In the absence of other cranial neuropathies, a CT scan with contrast from the skull base to the aorto-pulmonary window (the span of the recurrent laryngeal nerve) should be performed. If other cranial nerve deficits are noted, a

MRI scan of the brain and brainstem is warranted.

Unlike unilateral fold paralysis, bilateral fold paralysis usually causes inspiratory stridor with deep inspiration. If the onset of bilateral fold paralysis is insidious, it may be asymptomatic at rest and the patient may have a normal voice. However, the acute onset of bilateral vocal fold paralysis with inspiratory stridor at rest should be managed by a specialist immediately in a critical care environment. Causes of bilateral fold paralysis include thyroid surgery, esophageal cancer, and ventricular shunt malfunction. Unilateral or bilateral fold immobility may also be seen in cricoarytenoid arthritis secondary to advanced rheumatoid arthritis, intubation injuries, glottic and subglottic stenosis and, of course, laryngeal cancer. The goal of intervention is the creation of a safe airway with minimal reduction in voice quality and airway protection from aspiration. A number of fold lateralization procedures for bilateral paralysis have been advocated as a means of removing the tracheotomy tube.

Unilateral vocal fold paralysis is occasionally temporary and may take over a year to resolve spontaneously. Surgical management of persistent or irrecoverable symptomatic unilateral vocal fold paralysis has evolved over the last several decades. The primary goal is medialization of the paralyzed fold in order to create a stable platform for vocal fold vibration. Additional goals include improving pulmonary toilet by facilitating of cough and advancing diet. Success has been reported for years with injection laryngoplasty using Teflon, Gelfoam, fat and collagen. Teflon is the only permanent injectable material, but its use is discouraged because of granuloma formation within the vocal folds of some patients. Temporary injectable materials, such as collagen or fat, provide excellent temporary restoration of voice and can be placed under local or general anesthesia. Once the paralysis is determined to be permanent, formal medialization thyroplasty may be performed by creating a small window in the thyroid cartilage and placing an implant between the thyroarytenoid muscle and inner table of the thyroid cartilage. This procedure moves the vocal fold medially and creates a stable platform for bilateral, symmetric mucosal vibration.

Tracheostomy & Cricothyrotomy

There are two primary indications for tracheostomy: airway obstruction at or above the level of the larynx and respiratory failure requiring prolonged mechanical ventilation. In an acute emergency, cricothyrotomy secures an airway more rapidly than tracheostomy, with fewer potential immediate complications such as pneumothorax and hemorrhage. Percutaneous dilatational tracheostomy as an elective bedside (or intensive care unit) procedure has undergone scrutiny in recent years as an alternative to tracheostomy. In experienced hands, the various methods of percutaneous tracheostomy have been documented to be safe in carefully selected patients. Simultaneous videobronchoscopy can reduce the incidence of major complications. The major cost reduction comes from avoiding the operating room. Bedside tracheostomy (in the intensive care unit) achieves similar cost reduction and is advocated by some experts as slightly less costly than the percutaneous procedures.

The most common indication for elective tracheostomy is the need for prolonged mechanical ventilation. There is no firm rule about how many days a patient must be intubated before conversion to tracheostomy should be advised. The incidence of serious complications such as subglottic stenosis increases with extended endotracheal intubation. As soon as it is apparent that the patient will require protracted ventilatory support, tracheostomy should replace the endotracheal tube. Less frequent indications for tracheostomy are life-threatening aspiration pneumonia, the need to improve pulmonary toilet to correct problems related to insufficient clearing of tracheobronchial secretions, and sleep apnea.

Posttracheostomy care requires humidified air to prevent secretions from crusting and occluding the inner cannula of the tracheostomy tube. The tracheostomy tube should be cleaned several times daily. The most frequent early complication of tracheostomy is dislodgment of the tracheostomy tube. Surgical creation of an inferiorly based tracheal flap sutured to the inferior neck skin may make reinsertion of a dislodged tube easier. It should be recalled that the act of swallowing requires elevation of the larynx, which is limited by tracheostomy. Therefore, frequent tracheal and bronchial suctioning is often required to clear the aspirated saliva as well as the increased tracheobronchial secretions. Care of the skin around the stoma is important to prevent maceration and secondary infection.

Foreign Bodies in the Upper Aerodigestive Tract

Foreign Bodies of the Trachea & Bronchi

Aspiration of foreign bodies occurs less frequently in adults than in children. The elderly and denture wearers appear to be at greatest risk. Wider familiarity with the Heimlich maneuver has reduced deaths. If the maneuver is unsuccessful, cricothyrotomy may be necessary. Plain chest radiographs may reveal a radiopaque foreign body. Detection of radiolucent foreign bodies may be aided by inspiration-expiration films that demonstrate air trapping distal to the obstructed segment. Atelectasis and pneumonia may occur later.

Tracheal and bronchial foreign bodies should be removed under general anesthesia by a skilled endoscopist working with an experienced anesthesiologist.

Digoy GP. Diagnosis and management of upper aerodigestive tract foreign bodies. Otolaryngol Clin North Am. 2008 Jun;41(3):485–96. [PMID: 18435994]

Esophageal Foreign Bodies

Foreign bodies in the esophagus create urgent but not life-threatening situations as long as the airway is not compromised. There is probably time to consult an experienced clinician for management. Patients are likely to have difficulty handling secretions and may be spitting out their saliva. It is a useful diagnostic sign of complete obstruction if the patient is drooling or cannot handle secretions. They may often point to the exact level of the obstruction. Indirect laryngoscopy often shows pooling of saliva at the esophageal inlet. Plain films may detect radiopaque foreign bodies such as chicken bones. Coins tend to align in the coronal plane in the esophagus and sagittally in the trachea. If a foreign body is suspected, a barium swallow may help make the diagnosis.

The treatment of an esophageal foreign body depends very much on identification of its nature. In children, swallowed nonfood objects are common. In adults, however, food foreign bodies are more common, and there is the greater possibility of underlying esophageal pathology. Endoscopic removal and examination is usually best, via flexible esophagoscopy or rigid laryngoscopy and esophagoscopy. If there is nothing sharp such as a bone, some clinicians advocate a hospitalized 24-hour observation period prior to esophagoscopy, noting that spontaneous passage of the foreign body will occur in 50% of adult patients. In the management of meat obstruction, the use of papain (meat tenderizer) should be discouraged because it can damage the esophageal mucosa. Obstruction may sometimes occur from a metal stent placed in the treatment of esophageal cancer.

Thorac Surg. 2007 Dec;84(6):1854–7. [PMID: 18036898]

Neck Masses: Introduction

The differential diagnosis of neck masses is heavily dependent on the location in the neck, the age of the patient, and the presence of associated disease processes. Rapid growth and tenderness suggest an inflammatory process, while firm, painless, and slowly enlarging masses are often neoplastic. In young adults, most neck masses are benign (branchial cleft cyst, thyroglossal duct cyst, reactive lymphadenitis), although malignancy should always be considered (lymphoma, metastatic thyroid carcinoma). Lymphadenopathy is common in HIV-positive persons, but a growing or dominant mass may well represent lymphoma. In adults over age 40, cancer is the most common cause of persistent neck mass. A metastasis from SCC arising within the mouth, pharynx, larynx, or upper esophagus should be suspected, especially if there is a history of tobacco or significant alcohol use. Especially among patients younger than 30 or older than 70, lymphoma should be considered. In any case, a comprehensive otolaryngologic examination is needed. Cytologic evaluation of the neck mass via FNA biopsy is likely to be the next step if an obvious primary tumor is not obvious on physical examination.

Branchial Cleft Cysts

Branchial cleft cysts usually present as a soft cystic mass along the anterior border of the sternocleidomastoid muscle. These lesions are usually recognized in the second or third decades of life, often when they suddenly swell or become infected. To prevent recurrent infection and possible carcinoma, they should be completely excised, along with their fistulous tracts.

First branchial cleft cysts present high in the neck, sometimes just below the ear. A fistulous connection with the floor of the external auditory canal may be present. Second branchial cleft cysts, which are far more common, may communicate with the tonsillar fossa. Third branchial cleft cysts, which may communicate with the piriform sinus, are rare.

Acierno SP et al. Congenital cervical cysts, sinuses and fistulae. Otolaryngol Clin North Am. 2007 Feb;40(1):161–76. [PMID: 17346566]

Thyroglossal Duct Cysts

Thyroglossal duct cysts occur along the embryologic course of the thyroid's descent from the tuberculum impar of the tongue base to its usual position in the low neck. Although they may occur at any age, they are most common before age 20. They present as a midline neck mass, often just below the hyoid bone, which moves with swallowing. Surgical excision is recommended to prevent recurrent infection. This requires removal of the entire fistulous tract along with the middle portion of the hyoid bone through which many of the fistulas pass. Preoperative evaluation should include a thyroid ultrasound to confirm anatomic position of the thyroid.

Lin ST et al. Thyroglossal duct cyst: a comparison between children and adults. Am J Otolaryngol. 2008 Mar–Apr;29(2):83–7. [PMID: 18314017]

Reactive Cervical Lymphadenopathy

Normal lymph nodes in the neck are usually less than 1 cm in length. Infections involving the pharynx, salivary glands, and scalp often cause tender enlargement of neck nodes. Enlarged nodes are common in HIV-infected persons. Except for the occasional node that suppurates and requires incision and drainage, treatment is directed against the underlying infection. An enlarged node (> 1.5 cm) or node with a necrotic center that is not associated with an obvious infection should be further evaluated, especially if the patient has a history of smoking, alcohol use, or prior cancer. Other common indications for FNA biopsy of a node include its persistence or continued enlargement. Common causes of cervical adenopathy include tumor (SCC, lymphoma, occasional metastases from non-head and neck sites) and infection (eg, reactive nodes, mycobacteria [discussed below], and cat scratch disease). Rare causes of adenopathy include Kikuchi disease (histiocytic necrotizing lymphadenitis) and autoimmune adenopathy.

Ridder GJ et al. Role of cat-scratch disease in lymphadenopathy in the head and neck. Clin Infect Dis. 2002 Sep 15;35(6):643–9. [PMID: 12203159]

Tuberculous & Nontuberculous Mycobacterial Lymphadenitis

Granulomatous neck masses are not uncommon. The differential diagnosis includes mycobacterial adenitis, sarcoidosis, and cat-scratch disease due to *Bartonella henselae.* Although mycobacterial adenitis can extend to the skin and drain externally (as described for atypical mycobacteria and referred to as scrofula), this late presentation is no longer common. The usual presentation of granulomatous disease in the neck is simply single or matted nodes. FNA biopsy is usually the best initial diagnostic approach: cytology, smear for acid-fast bacilli, culture, and sensitivity test; and polymerase chain reaction (PCR) can all be done.

Mycobacterial lymphadenitis is on the rise both in immunocompromised and immunocompetent individuals. Identification of *Mycobacterium tuberculosis* can usually be confirmed by a combination of FNA smear and culture, but excisional biopsy of a node may be needed. PCR from FNA (or from excised tissue) is the single most sensitive test and is particularly useful when conventional methods have not been diagnostic but clinical impression remains consistent for tuberculous infection.

Short-course therapy (6 months) consisting of an initial 4 months of streptomycin, isoniazid, rifampin, and pyrazinamide followed by 2 months of rifampin is the current recommended treatment for tuberculous lymphadenopathy (see Table 9–11). For atypical (nontuberculous) lymphadenopathy, treatment depends on sensitivity results of culture, but antibiotics likely to be useful include 6 months of isoniazid and rifampin and, for at least the first 2 months, ethambutol—all in standard dosages. Some would totally excise the involved nodes prior to chemotherapy, depending on location and other factors, but this can lead to chronic draining fistulas.

Lyme Disease

Lyme disease, caused by the spirochete *Borrelia burgdorferi* and transmitted by ticks of the *Ixodes* genus, may have protean manifestation, but over 75% of patients have symptoms involving the head and neck. Facial paralysis, dysesthesias, dysgeusia, or other cranial neuropathies are most common. Headache, pain, and cervical lymphadenopathy may occur. See Chapter 34: Spirochetal Infections for a more detailed discussion.

Ljostad U et al. Acute peripheral facial palsy in adults. J Neurol. 2005 Jun;252(6):672–6. [PMID: 15778908]

Tumor Metastases

In older adults, 80% of firm, persistent, and enlarging neck masses are metastatic in origin. The great majority of these arise from SCC of the upper aerodigestive tract. A complete head and neck examination may reveal the tumor of origin, but examination under anesthesia with direct laryngoscopy, esophagoscopy, and bronchoscopy is usually required to fully evaluate the tumor and exclude second primaries.

It is often helpful to obtain a cytologic diagnosis if initial head and neck examination fails to reveal the primary tumor. An open biopsy should be done only when neither physical examination by an experienced clinician specializing in head and neck cancer nor FNA biopsy performed by an experienced cytopathologist yields a diagnosis. In such a setting, one should strongly consider obtaining an MRI or PET scan prior to open biopsy, as these methods may yield valuable information about a possible presumed primary site or another site for FNA.

With the exception of papillary thyroid carcinoma, non–squamous cell metastases to the neck are infrequent. While tumors that are not primary in the head or neck seldom metastasize to the cervical lymph nodes, the supraclavicular lymph nodes are quite often involved by lung, gastroesophageal, and breast tumors. Infradiaphragmatic tumors, with the exception of renal cell carcinoma and testicular cancer, rarely metastasize to the neck.

Landry CS et al. The evolution of the management of regional lymph nodes in melanoma. J Surg Oncol. 2007 Sep 15;96(4):316–21. [PMID: 17879333]

Lymphoma

About 10% of lymphomas present in the head and neck. Lymphoma arising in AIDS patients is an increasing concern. Multiple rubbery nodes, especially in the young adult, are suggestive of this disease. A thorough physical examination may demonstrate other sites of nodal or organ involvement. FNA biopsy may be diagnostic, but open biopsy is often required to determine architecture and an appropriate treatment course.

Howlett DC et al. Diagnostic adequacy and accuracy of fine needle aspiration cytology in neck lump assessment: results from a regional cancer network over a one year period. J Laryngol Otol. 2007 Jun;121(6):571–9. [PMID: 17134537]

Physical Examination

Examination of the patient with suspected pulmonary disease includes inspection, palpation, percussion, and auscultation of the chest. An efficient approach begins with observing the pattern of breathing, auscultation of the chest, and inspection for extrapulmonary signs of pulmonary disease. More detailed examination follows from initial findings.

The pattern of breathing refers to the respiratory rate and rhythm, the depth of breathing or tidal volume, and the relative amount of time spent in inspiration and expiration. Normal values are a rate of 12–14 breaths per minute, tidal volumes of 5 mL/kg, and a ratio of inspiratory to expiratory time of approximately 2:3.

Tachypnea is an increased rate of breathing and is commonly associated with a decrease in tidal volume. Respiratory rhythm is normally regular, with a sigh (1.5–2 times normal tidal volume) every 90 breaths or so to prevent collapse of alveoli and atelectasis. Alterations in the rhythm of breathing include rapid, shallow breathing, seen in restrictive lung disease and as a precursor to respiratory failure; **Kussmaul** breathing, rapid large-volume breathing indicating intense stimulation of the respiratory center, seen in metabolic acidosis; and **Cheyne-Stokes** respiration, a rhythmic waxing and waning of both rate and tidal volumes that includes regular periods of apnea. This last pattern is seen in patients with end-stage left ventricular failure or neurologic disease and in many normal persons at high altitude, especially during sleep.

During normal quiet breathing, the primary muscle of respiration is the diaphragm. Movement of the chest wall is minimal. The use of accessory muscles of respiration, the intercostal and sternocleidomastoid muscles, indicates high work of breathing. At rest, the use of accessory muscles is a sign of significant pulmonary impairment. As the diaphragm contracts, it pushes the abdominal contents down. Hence, the chest and abdominal wall normally expand simultaneously. Expansion of the chest but collapse of the abdomen on inspiration indicates weakness of the diaphragm. The chest normally expands symmetrically. Asymmetric expansion suggests unilateral volume loss, as in atelectasis or pleural effusion, unilateral airway obstruction, asymmetric pulmonary or pleural fibrosis, or splinting from chest pain.

The examiner may palpate as follows: the trachea at the suprasternal notch, to detect shifts in the mediastinum; on the posterior chest wall, to gauge fremitus and the transmission through the lungs of vibrations of spoken words; and on the anterior chest wall to assess the cardiac impulse. All these maneuvers are characterized by low interobserver agreement.

Chest percussion identifies dull areas that correspond to lung consolidation or pleural effusion or hyperresonant areas suggesting emphysema or pneumothorax. Percussion has a low sensitivity (10–20% in several studies) compared with chest radiographs to detect abnormalities. Specificity is high (85–99%). Since an insensitive test is a poor screening examination, percussion and palpation are not necessary in every patient. These techniques do serve as important confirmatory tests in specific patients when the prior probability of a finding is increased. For example, in a patient with a suspected tension pneumothorax, the finding of tracheal shift and hyperresonance can be lifesaving, permitting immediate decompression of the affected side.

Auscultation of the chest depends on a reliable and consistent classification of auditory findings. Normal lung sounds heard over the periphery of the lung are called **vesicular** ; . They have a gentle, rustling quality heard throughout inspiration that fades during expiration. Normal sounds heard over the suprasternal notch are called tracheal or **bronchial** lung sounds . They are louder, higher-pitched, and have a hollow quality that tends to be louder on expiration. Bronchial lung sounds heard over the periphery of the lung are abnormal and imply consolidation. Globally diminished lung sounds are an important finding predictive of significant airflow obstruction .

Audio
Recording of normal vesicular lung sounds. (Reproduced, with permission, from Raymond L.H. Murphy, Jr., MD: *A Simplified Introduction to Lung Sounds* [audio tape], 1977.)

Audio
Bronchial breath sounds recorded over an area of consolidation in a person with pneumonia. Note the loud expiratory phase, which helps to clarify these sounds as bronchial. (Reproduced, with permission, from Raymond L.H. Murphy, Jr., MD: *A Simplified Introduction to Lung Sounds* [audio tape], 1977.)

Audio
Recording of breath sounds in a person with emphysema. Note the diminished intensity of breath sounds in emphysema. The obstruction to air flow is more severe in expiration than in inspiration, and expiration is prolonged. (Reproduced, with permission, from Raymond L.H. Murphy, Jr., MD: *A Simplified Introduction to Lung Sounds* [audio tape], 1977.)

Abnormal lung sounds ("adventitious" breath sounds) may be continuous (> 80 ms in duration) or discontinuous (< 20 ms). Continuous lung sounds are divided into **wheezes** , which are high-pitched, musical, and have a distinct whistling quality; and **rhonchi** , which are lower-pitched, sonorous, and may have a gurgling quality. Wheezes occur in the setting of bronchospasm, mucosal edema, or excessive secretions. In each case, the airway is narrowed to the point where adjacent airway walls flutter as airflow is limited. Rhonchi originate in the larger airways when excessive secretions and abnormal airway collapsibility cause repetitive rupture of fluid films. Rhonchi frequently clear after cough.

Audio
Lung sound: sibilant rhonchus, often called "wheezes." (Reproduced, with permission, from Raymond L.H. Murphy, Jr., MD: *A Simplified Introduction to Lung Sounds* [audio tape], 1977.)

Audio
Lung sound: sonorous rhonchus. (Reproduced, with permission, from Raymond L.H. Murphy, Jr., MD: *A Simplified Introduction to Lung Sounds* [audio tape], 1977.)

Discontinuous lung sounds are called **crackles**—brief, discrete, nonmusical sounds with a popping quality. Fine crackles are soft, high-pitched, and crisp (< 10 ms in duration). They are formed by the explosive opening of small airways previously held closed by surface forces and are heard in interstitial diseases or early pulmonary edema. Coarse crackles are louder, lower-pitched, and slightly longer in duration (< 20 ms) and probably result from gas bubbling through fluid . Coarse crackles are heard in pneumonia, obstructive lung disease, and late pulmonary edema.

Audio
Discontinuous lung sound: fine rales. Note that, in general, each individual rale is less loud and of shorter duration than the coarse rales. (Reproduced, with permission, from Raymond L.H. Murphy, Jr., MD: *A Simplified Introduction to Lung Sounds* [audio tape], 1977.)

Audio
Discontinuous lung sound: coarse rales. (Reproduced, with permission, from Raymond L.H. Murphy, Jr., MD: *A Simplified Introduction to Lung Sounds* [audio tape], 1977.)

Interobserver agreement regarding auscultatory findings is good. The clinical usefulness of these findings is also well established. The presence of wheezes on physical examination is a powerful predictor of obstructive lung disease. The absence of wheezes is not helpful since patients may have significant airflow limitation without wheezing. Such patients will have globally diminished lung sounds as the clinical clue to their obstructive lung disease. Normal lung sounds exclude significant airway obstruction. The timing and character of crackles can reliably distinguish different pulmonary disorders. Fine, late inspiratory crackles suggest pulmonary fibrosis, while early coarse crackles suggest pneumonia or heart failure.

Extrapulmonary signs of intrinsic pulmonary disease include digital clubbing, cyanosis, elevation of central venous pressures, and lower extremity edema.

Digital clubbing (see photograph) refers to structural changes at the base of the nails that include softening of the nail bed and loss of the normal 150-degree angle between the nail and the cuticle. The distal phalanx is convex and enlarged: its thickness is equal to or greater than the thickness of the distal interphalangeal joint. Symmetric clubbing may be a normal variant but more commonly is a sign of underlying disease. Clubbing is seen in patients with chronic infections of the lungs and pleura (lung abscess, empyema, bronchiectasis, cystic fibrosis), malignancies of the lungs and pleura, chronic interstitial lung disease (idiopathic pulmonary fibrosis), and arteriovenous malformations. It does not normally accompany asthma or COPD; when seen in the latter, concomitant lung cancer should be suspected. It is observed less often in small-cell cancer than in other histologic types. Clubbing is not specific to pulmonary disorders; it is also seen in cyanotic congenital heart disease, infective endocarditis, cirrhosis, and inflammatory bowel disease. **Hypertrophic pulmonary osteoarthropathy** is a syndrome of digital clubbing, chronic proliferative periostitis of the long bones, and synovitis. It is seen in the same conditions as digital clubbing but is particularly common in bronchogenic carcinoma. The cause of clubbing and hypertrophic osteoarthropathy is not known with certainty, but the disorder may reflect platelet clumping and local release of platelet-derived growth factor at the nail bed. Both clubbing and osteoarthropathy may resolve with appropriate treatment of the underlying disease.

Cyanosis is a blue or bluish-gray discoloration of the skin and mucous membranes caused by increased amounts (> 5 g/dL) of unsaturated hemoglobin in capillary blood. Since the oxygen saturation at which cyanosis becomes clinically apparent is a function of hemoglobin concentration, anemia may prevent cyanosis from appearing while polycythemia may lead to cyanosis in the setting of mild hypoxemia. Cyanosis is therefore not a reliable indicator of hypoxemia but should prompt direct measurement of arterial PO_2 or of hemoglobin saturation.

Estimation of **central venous pressure** (CVP) (see illustration) and assessment of lower extremity edema are indirect measures of pulmonary hypertension, the major cardiovascular complication of chronic lung disease. Estimation of CVP can be done with precision in many patients. Elevated CVP is a pathologic finding associated with impaired ventricular function, pericardial effusion or restriction, valvular heart disease, and chronic obstructive or restrictive lung disease. Peripheral edema is a nonspecific finding that, in the setting of chronic lung disease, suggests right ventricular failure.

Pulmonary Function Tests

Standard pulmonary function tests measure airflow rates, lung volumes, and the ability of the lung to transfer gas across the alveolar-capillary membrane. Indications for pulmonary function testing include assessment of the type and extent of lung dysfunction; diagnosis of causes of dyspnea and cough; detection of early evidence of lung dysfunction; longitudinal surveillance in occupational settings; follow-up of response to therapy; preoperative assessment; and disability evaluation.

Contraindications to pulmonary function testing include acute severe asthma, respiratory distress, angina aggravated by testing, pneumothorax, ongoing hemoptysis, and active tuberculosis. Many test results are effort-dependent, and some patients may be too impaired to make a maximal effort. Suboptimal effort limits validity and is a common cause of misinterpretation of results. All pulmonary function tests are measured against predicted values derived from large studies of healthy subjects. In general, these predictions vary with age, gender, height and, to a lesser extent, weight and ethnicity.

Spirometry (see box) and measurement of lung volumes allow assessment of the presence and severity of obstructive and restrictive pulmonary dysfunction. Obstructive dysfunction is marked by a reduction in airflow rates judged by a fall in the ratio of FEV_1 (forced expiratory volume in the first second) to FVC (forced vital capacity). Causes include asthma, COPD (chronic bronchitis and emphysema), bronchiectasis, bronchiolitis, and upper airway obstruction. Restrictive dysfunction is marked by a reduction in lung volumes with a normal to increased FEV_1/FVC ratio. Severity is graded by the reduction in total lung capacity. A reduced FVC suggests pulmonary restriction but is not diagnostic. Causes include decreased lung compliance from infiltrative disorders such as pulmonary fibrosis; reduced muscle strength from phrenic nerve injury, diaphragm dysfunction, or neuromuscular disease; pleural disease, including large pleural effusion or marked pleural thickening; and prior lung resection. The flow-volume loop combines the maximal expiratory and inspiratory flow-volume curves and is especially helpful in determining the site of airway obstruction. (See eFigure 9–1.0: illustration.)

Lung volumes, capacities, and the normal spirogram.
The volume of gas in the lungs is divided into volumes and capacities as shown in the bars to the left of the figure below. Lung volumes are primary: they do not overlap each other. Tidal volume (VT) is the amount of gas inhaled and exhaled with each resting breath. Residual volume (RV) is the amount of gas remaining in the lungs at the end of a maximal exhalation. The vital capacity (VC) is the total amount of gas that can be exhaled following a maximal inhalation. The vital

capacity and the residual volume together constitute the total lung capacity (TLC), or the total amount of gas in the lungs at the end of a maximal inhalation. The functional residual capacity (FRC) is the amount of gas in the lungs at the end of a resting tidal breath. (IC = inspiratory capacity; IRV= inspiratory reserve volume; ERV = expiratory reserve volume.)

The forced vital capacity (FVC) maneuver begins with an inhalation from FRC to TLC (lasting about 1 second) followed by a forceful exhalation from TLC to RV (lasting about 5 seconds). The amount of gas exhaled during the first second of this maneuver is the forced expiratory volume in the first second (FEV_1). Normal subjects expel approximately 80% of the FVC in the first second. The ratio of the FEV_1 to the FVC (often referred to as the FEV_1%) is diminished in patients with obstructive lung disease. It may be increased in patients with restrictive physiology.

Modified, with permission, from Comroe JH et al: *The Lung: Clinical Physiology and Pulmonary Function Tests*, 2nd ed. Year Book Medical Publishers, 1962.

eFigure 9–1.0.

Representative spirograms (upper panel) and expiratory flow-volume curves (lower panel) for normal *(A)*, obstructive *(B)*, and restrictive *(C)* patterns.

Spirometry is adequate for evaluation of most patients with suspected respiratory disease. If airflow obstruction is evident, spirometry may be repeated 10–20 minutes after an inhaled bronchodilator is administered. The absence of improvement in spirometry after inhaled bronchodilator in the pulmonary function laboratory does *not* preclude a successful clinical response to bronchodilator therapy. Measurements of lung volumes and diffusing capacity are useful in selected patients, but these tests are expensive and should not be ordered routinely with spirometry.

Measurement of the single-breath **diffusing capacity** for carbon monoxide (DL_{CO}), which reflects the ability of the lung to transfer gas across the alveolar/capillary interface, is particularly helpful in evaluation of patients with diffuse infiltrative lung disease or emphysema. The total pulmonary diffusing capacity depends upon the diffusion properties of the alveolar-capillary membrane and the amount of hemoglobin occupying the pulmonary capillaries. The diffusing capacity should therefore be corrected for the blood hemoglobin concentration.*

*Corrected DL_{CO} = Measured DL_{CO} x (1.7 Hb/(10.22+Hb), where [Hb] is the measured hemoglobin concentration (g/dL).

Elevated DL_{CO} is observed in pulmonary hemorrhage and may be seen in acute congestive heart failure and asthma due to an increase in pulmonary capillary blood volume. Reporting the ratio of measured diffusing capacity to alveolar volume (DL_{CO} /VA) is helpful, because a diminished diffusing capacity may only reflect a reduction in the breath taken during the maneuver. In patients with emphysema, the diffusing capacity is characteristically low, the alveolar volume normal or increased, and the DL_{CO} /VA ratio is low. In patients with diffuse infiltrative lung disease, both the diffusing capacity and the alveolar volume are characteristically reduced, and the DL_{CO} /VA ratio is normal or low.

In patients with AIDS, DL_{CO} is a highly sensitive screening test for the presence of pulmonary disease, especially *Pneumocystis jiroveci* (formerly *P carinii*) pneumonia, but it lacks specificity. A normal DL_{CO} in an AIDS patient is strong evidence against *Pneumocystis* pneumonia.

Arterial blood gas analysis is indicated whenever a clinically important acid-base disturbance, hypoxemia, or hypercapnia is suspected. Oximetry provides an inexpensive, noninvasive alternative means of monitoring hemoglobin saturation with oxygen. Oximeters monitor oxygen saturation and not oxygen tension. eFigure 9–1.1: illustration displays the normal relationship between oxygen saturation and partial pressure of oxygen in blood. This relationship is not linear. The clinical accuracy of pulse oximeters is reduced in such conditions as severe anemia (< 5 g/dL hemoglobin), the presence of abnormal hemoglobin moieties (carboxyhemoglobin, methemoglobin, fetal hemoglobin), the presence of intravascular dyes, motion artifact, and lack of pulsatile arterial blood flow (hypotension, hypothermia, cardiac arrest, simultaneous use of a blood pressure cuff, and cardiopulmonary bypass). Co-oximetry, a form of oximetry that uses additional wavelengths of light to identify oxyhemoglobin and deoxyhemoglobin, can identify the more common abnormal hemoglobins. The normal arterial PO_2 falls with increasing altitude (eTable 9–1.0).

eTable 9–1.0. The effect of altitude on PO_2 in normal adults.

Altitude (feet)	**Barometric Pressure (mm Hg)**	**Atmospheric[1] PO_2 (mm Hg)**	**Tracheal[2] PO_2 (mm Hg)**	**Arterial[3] PO_2 (mm Hg)**
Sea level	760	159	149	99
2000	707	148	138	88
4000	656	137	127	77
6000	609	127	118	68
8000	564	118	108	58
10,000	523	109	100	50
15,000	426	90	80	30

[1] Dry gas.

[2] Saturated with water vapor.

[3] Actual values at altitude will be higher, depending on the degree of adaptation (ventilatory response to hypoxia).

Nonspecific **bronchial provocation testing** may aid the evaluation of suspected asthma, when baseline spirometry is normal, and in unexplained cough. The subject inhales a nebulized solution containing methacholine or histamine. These agents cause bronchial smooth muscle constriction in asthmatic patients at much lower doses than in nonasthmatics. If the FEV_1 falls by more than 20% at a dose of 16 mg/mL or less, the test is positive. Bronchial provocation testing is 95% sensitive for the diagnosis of asthma. A negative result therefore makes asthma unlikely. Specificity is lower—about 70%—since false positives may occur in several common conditions, including COPD, congestive heart failure, recent viral respiratory infection, cystic fibrosis, and sarcoidosis.

Cardiopulmonary Exercise Stress Testing

Cardiopulmonary exercise testing is usually performed to evaluate patients with unexplained exertional dyspnea. A bicycle ergometer or treadmill is used. Minute ventilation, expired oxygen and carbon dioxide tension, heart rate, blood pressure, and respiratory rate are monitored. The exercise protocol is determined by the indications for the test and the ability of the patient to exercise. Certain patterns of abnormal oxygen uptake or delivery can be identified and may lead to specific pulmonary or cardiac diagnoses. The test is also used to quantify cardiorespiratory capacity. Complications are rare.

Bronchoscopy

Flexible bronchoscopy (see photograph); (see illustration) is an essential tool in the diagnosis and management of many pulmonary diseases. Bronchoscopy is indicated for evaluation of the airway, diagnosis and staging of bronchogenic carcinoma, evaluation of hemoptysis, and diagnosis of pulmonary infections. It allows transbronchial lung biopsy (see illustration), bronchoalveolar lavage, and removal of retained secretions and foreign bodies from the airway. procedure is contraindicated in severe bronchospasm or a bleeding diathesis. Complications include hemorrhage, fever, and transient hypoxemia. The rate of major complications is less than 1% but increases to about 7% when transbronchial lung biopsy is performed. Deaths are rare. Hospitalization for flexible bronchoscopy is not necessary.

Fig.

Forceps biopsy of cancer, left main stem bronchus.

(Reproduced, with permission, from Stradling P: *Diagnostic Bronchoscopy*. Churchill Livingstone, 1981.)

Rigid bronchoscopy is performed for massive bleeding, extraction of large obstructing objects (foreign bodies, blood clots, tumor masses, broncholiths), biopsy of tracheal or main stem bronchus tumors and bronchial carcinoids, and facilitation of laser therapy. Unlike flexible bronchoscopy, which can usually be performed with only topical anesthesia and low-dose conscious sedation (an opioid or a benzodiazepine or both), rigid bronchoscopy usually requires general anesthesia.

Advances in techniques including endobronchial laser therapy, electrocautery, tracheobronchial stenting, and endobronchial ultrasound guidance to locate lymph nodes prior to transbronchial needle aspiration biopsy promise to expand diagnostic and therapeutic avenues available to the bronchoscopist significantly. This is an area of rapid technological advancement and emerging clinical research study.

Disorders of the Airways: Introduction

Airway disorders have diverse causes but share certain common pathophysiologic and clinical features. Airflow limitation is characteristic and frequently causes dyspnea and cough. Other symptoms are common and typically disease-specific. Disorders of the airways can be classified as those that involve the upper airways—loosely defined as those above and including the vocal folds—and those that involve the lower airways.

Disorders of the Upper Airways

Upper airway obstruction may occur acutely or present as a chronic condition. **Acute upper airway obstruction** can be immediately life-threatening and must be relieved promptly to avoid asphyxia. Causes of acute upper airway obstruction include trauma to the larynx or pharynx, foreign body aspiration, laryngospasm, laryngeal edema from thermal injury or angioedema, infections (acute epiglottitis, Ludwig angina, pharyngeal or retropharyngeal abscess), and acute allergic laryngitis.

Chronic obstruction of the upper airway may be caused by carcinoma of the pharynx or larynx, laryngeal or subglottic stenosis, laryngeal granulomas or webs, or bilateral vocal fold paralysis. Laryngeal or subglottic stenosis may become evident weeks or months following a period of translaryngeal endotracheal intubation. Inspiratory stridor, intercostal retractions on inspiration, a palpable inspiratory thrill over the larynx, and wheezing localized to the neck or trachea on auscultation are characteristic findings. Flow-volume loops may show flow limitations characteristic of obstruction. Soft tissue radiographs of the neck may show supraglottic or infraglottic narrowing. CT and MRI scans can reveal exact sites of obstruction. Flexible endoscopy may be diagnostic, but caution is necessary to avoid exacerbating upper airway edema and precipitating critical airway narrowing.

Vocal fold dysfunction syndrome is a condition characterized by paradoxical vocal fold adduction, resulting in both acute and chronic upper airway obstruction. It can cause dyspnea and wheezing that may present as asthma or exercise-induced asthma but may be distinguished from asthma by the lack of response to bronchodilator therapy, normal spirometry immediately after an attack, spirometric evidence of upper airway obstruction, a negative bronchial provocation test, or direct visualization of adduction of the vocal folds on both inspiration and expiration. The condition appears to be psychogenic in nature. Bronchodilators are of no therapeutic benefit. Treatment consists of speech therapy, which uses breathing, voice, and neck relaxation exercises to abort the symptoms.

Mikita JA et al. Vocal cord dysfunction. Allergy Asthma

Proc. 2006 Jul–Aug;27(4):411–4. [PMID: 16948360]

Sohrab S et al. Management of central airway obstruction. Clin Lung Cancer. 2007 Mar;8(5):305–12. [PMID: 17562229]

Disorders of the Lower Airways

Tracheal obstruction may be intrathoracic (below the suprasternal notch) or extrathoracic. Fixed tracheal obstruction may be caused by acquired or congenital tracheal stenosis, primary or secondary tracheal neoplasms, extrinsic compression (tumors of the lung, thymus, or thyroid; lymphadenopathy; congenital vascular rings; aneurysms, etc), foreign body aspiration, tracheal granulomas and papillomas, and tracheal trauma.

Acquired **tracheal stenosis** is usually secondary to previous tracheotomy or endotracheal intubation. Dyspnea, cough, and inability to clear pulmonary secretions occur weeks to months after tracheal decannulation or extubation. Physical findings may be absent until tracheal diameter is reduced 50% or more, when wheezing, a palpable tracheal thrill, and harsh breath sounds may be detected . The diagnosis is usually confirmed by plain films or CT of the trachea. Complications include recurring pulmonary infection and life-threatening respiratory failure. Management is directed toward ensuring adequate ventilation and oxygenation and avoiding manipulative procedures that may increase edema of the tracheal mucosa. Surgical reconstruction, endotracheal stent placement, or laser photoresection may be required.

Audio
Recording of a person with tracheal stenosis. Note the high-pitched sound of inspiratory stridor. (Reproduced, with permission, from Raymond L.H. Murphy, Jr., MD: *A Simplified Introduction to Lung Sounds* [audio tape], 1977.)

Bronchial obstruction may be caused by retained pulmonary secretions, aspiration, foreign bodies, bronchogenic carcinoma, compression by extrinsic masses, and tumors metastatic to the airway. Clinical and radiographic findings vary depending on the location of the obstruction and the degree of airway narrowing. Symptoms include dyspnea, cough, wheezing, and, if infection is present, fever and chills. A history of recurrent pneumonia in the same lobe or segment or slow resolution (> 3 months) of pneumonia on successive radiographs suggests the possibility of bronchial obstruction and the need for bronchoscopy.

Roentgenographic findings include **atelectasis** (local parenchymal collapse), postobstructive infiltrates, and air trapping caused by unidirectional expiratory obstruction. CT scanning may demonstrate the nature and the exact location of obstruction of the central bronchi. MRI may be superior to CT for delineating the extent of underlying disease in the hilum, but it is usually reserved for cases in which CT findings are equivocal. Bronchoscopy is the definitive diagnostic study, particularly if tumor or foreign body aspiration is suspected. The finding of bronchial breath sounds on physical examination or an air bronchogram on chest radiograph in an area of atelectasis rules out complete airway obstruction . Bronchoscopy is unlikely to be of therapeutic benefit in this situation.

Audio
Recording of a person with atelectasis. It shows slight bronchial breathing and fine inspiratory rales. (Reproduced, with permission, from Raymond L.H. Murphy, Jr., MD: *A Simplified Introduction to Lung Sounds* [audio tape], 1977.)

Right middle lobe syndrome is recurrent or persistent atelectasis of the right middle lobe. This collapse is related to the relatively long length and narrow diameter of the right middle lobe bronchus and the oval ("fish mouth") opening to the lobe, in the setting of impaired collateral ventilation. Fiberoptic bronchoscopy or CT scan is often necessary to rule out obstructing tumor. Foreign body or other benign causes are common.

Kwon KY et al. Middle lobe syndrome: a clinicopathological study of 21 patients. Hum Pathol. 1995 Mar;26(3):302–7. [PMID: 7890282]

Asthma

Essentials of Diagnosis

- Episodic or chronic symptoms of airflow obstruction: breathlessness, chest tightness, wheezing, and cough.
- Complete or partial reversibility of airflow obstruction, either spontaneously or following bronchodilator therapy.
- Symptoms frequently worse at night or in the early morning.
- Prolonged expiration and diffuse wheezes on physical examination.
- Limitation of airflow on pulmonary function testing or positive bronchoprovocation challenge.

General Considerations

Asthma is a common disease, affecting approximately 5% of the population. It is slightly more common in male children (< 14 years old) and in female adults. A genetic predisposition to asthma is recognized. Prevalence, hospitalizations, and fatal asthma have all increased in the United States over the past 20 years. Each year, approximately 470,000 hospital admissions and 5000 deaths in the United States are attributed to asthma. Hospitalization rates have been highest among blacks and children, and death rates for asthma are consistently highest among blacks aged 15–24 years.

Definition & Pathogenesis

Asthma is a chronic inflammatory disorder of the airways. No single histopathologic feature is pathognomonic but common findings include inflammatory cell infiltration with eosinophils, neutrophils, and lymphocytes (especially T lymphocytes); goblet cell hyperplasia, sometimes with plugging of small airways with thick mucus; collagen deposition beneath the basement membrane; hypertrophy of bronchial smooth muscle; airway edema; mast cell activation; and denudation of airway epithelium. This airway inflammation underlies disease chronicity and contributes to airway hyper-responsiveness, airflow limitation, and respiratory symptoms, including recurrent episodes of wheezing, breathlessness, chest tightness, and cough.

The strongest identifiable predisposing factor for the development of asthma is atopy, but obesity is increasingly recognized as a risk factor. Exposure of sensitive patients to inhaled allergens increases airway inflammation, airway hyper-responsiveness, and symptoms. Symptoms may develop immediately (immediate asthmatic response) or 4–6 hours after allergen exposure (late asthmatic response). Common allergens include house dust mites (often found in pillows, mattresses, upholstered furniture, carpets, and drapes), cockroaches, cat dander, and seasonal pollens. Substantially reducing exposure reduces pathologic findings and clinical symptoms.

Nonspecific precipitants of asthma include exercise, upper respiratory tract infections, rhinitis, sinusitis, postnasal drip, aspiration, gastroesophageal reflux, changes in the weather, and stress. Exposure to environmental tobacco smoke increases asthma symptoms and the need for medications and reduces lung function. Increased air levels of respirable particles, ozone, SO_2, and NO_2 precipitate asthma symptoms and increase emergency department visits and hospitalizations. Selected individuals may experience asthma symptoms after exposure to aspirin, nonsteroidal anti-inflammatory drugs, or tartrazine dyes. Certain other medications may also precipitate asthma symptoms (see Table 9–21). Occupational asthma is triggered by various agents in the workplace and may occur weeks to years after initial exposure and sensitization. Women may experience catamenial asthma at predictable times during the menstrual cycle. Exercise-induced bronchoconstriction begins during exercise or within 3 minutes after its end, peaks within 10–15 minutes, and then resolves by 60 minutes. This phenomenon is thought to be a consequence of the airways' attempt to warm and humidify an increased volume of expired air during exercise. "Cardiac asthma" is wheezing precipitated by uncompensated congestive heart failure.

Clinical Findings

Symptoms and signs vary widely from patient to patient as well as individually over time. General clinical findings in stable asthma patients are listed in Figure 9–1 and Table 9–1; findings seen during asthma exacerbations are listed in Tables 9–2 and 9–3.

Figure 9–1.

Classifying asthma severity and initiating treatment.

(Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. Bethesda, MD, 2007.

http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm)

Table 9–1. Assessing asthma control.

		Classification of Asthma Control		
Components of control		**Well Controlled**	**Not Well Controlled**	**Very Poorly Controlled**
Impairment	Symptoms	2 days/week	>2 days/week	Throughout the day
	Nighttime awakenings	2x/month	1–3x/week	4x/week
	Interference with normal activity	None	Some limitation	Extremely limited
	Short-acting $_2$-agonist use for symptom control	2 days/week	>2 days/week	Several times/day

	(not prevention of EIB)			
	FEV_1 or peak flow	>80% predicted/personal best	60–80% predicted/personal best	<60% predicted/personal best
	Validated questionnaires			
	ATAQ	0	1–2	3–4
	ACQ	0.75[1]	1.5	N/A
	ACT	20	16–19	15
Risk	Exacerbations requiring oral system corticosteroids	0–1/year	2/year (see note)	
		Consider severity and interval since last exacerbation		
	Progressive loss of	Evaluation requires long-term follow-up care		

	lung function			
	Treatment-related adverse effects	Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk.		
Recommended Action for Treatment		• Maintain in current step • Regular follow-ups every 1–6 months to maintain control. • Consider step	• Step up 1 step and • Reevaluate in 2–6 weeks. • For side effects, consider alternative treatment options	• Consider short course of oral systemic corticosteroids, • Step up 1–2 steps, and • Reevaluate in 2 weeks • For

	down if well controlled for at least 3 months	.	side effects, consider alternative treatment options.

[1] ACQ values of 0.76–1.4 are indeterminate regarding well-controlled asthma.

EIB, exercise-induced bronchospasm; ICU, intensive care unit.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision-making required to meet individual patient needs.
- The level of control is based on the most severe impairment or risk category. Assess impairment domain by patient's recall of previous 2–4 weeks and by spirometry or peak flow measures. Symptom assessment for longer periods should reflect a global

assessment, such as inquiring whether the patient's asthma is better or worse since the last visit.

- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (eg, requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate poorer disease control. For treatment purposes,

  patients who had 2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have not-well-controlled asthma, even in the absence of impairment levels consistent with not-well-controlled asthma.
- Validated Questionnaires for the impairment domain (the questionnaire did not assess lung function or the risk domain).
- ATAQ = Asthma Therapy Assessment Questionnaire©
- ACQ = Asthma Control Questionnaire© (user package may be obtained at http://www.qoltech.co.uk or juniper@qoltech.co.uk)
- ACT = Asthma Control Test™
- Minimal Importance Difference: 1.0 for the ATAQ; 0.5 for the ACQ; not determined for the ACT.
- Before step up in therapy:

  —Review adherence to medication, inhaler
  —If an alternative treatment option was used in a

step, discontinue and use the preferred treatment for that step.

Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. Bethesda, MD, 2007. http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm.

Table 9–2. Classifying severity of asthma exacerbations.

Note: Patients are instructed to use quick-relief medications if symptoms occur or if PEF drops below 80% predicted or personal best. If PEF is 50–79%, the patient should monitor response to quick relief medications carefully and consider contacting a clinician. If PEF is below 50%, immediate medical care is usually required. In the urgent or emergency care setting, the following parameters describe the severity and likely clinical course of an exacerbation.

	Symptoms and Signs	**Initial PEF (or FEV_1)**	**Clinical Course**
Mild	Dyspnea only with activity	PEV 70% predicted	Usually cared for at home Prompt relief

	(assess tachypnea in young children)	or personal best	with inhaled SABA
			Possible short course of oral systemic corticosteroids
Moderate	Dyspnea interferes with limits of usual activity	PEF 40–69% predicted or personal best	Usually requires office or ED visit
			Relief from frequent inhaled SABA
			Oral systemic corticosteroids; some symptoms last for 1–2 days after treatment is begun
Severe	Dyspnea at rest; interferes with conversation	PEF < 40% predicted or personal best	Usually requires ED visit and likely hospitalization
			Partial relief from frequent inhaled SABA
			Oral systemic corticosteroids; some symptoms last

			for > 3 days after treatment is begun
			Adjunctive therapies are helpful
Subset: Life-threatening	Too dyspneic to speak; perspiring	PEF < 25% predicted or personal best	Requires ED/hospitalization; possible ICU
			Minimal or no relief from frequent inhaled SABA
			Intravenous corticosteroids
			Adjunctive therapies are helpful

ED, emergency department; FEV_1, forced expiratory volume in 1 second; ICU, intensive care unit; PEF, peak expiratory flow; SABA, short-acting ${}_2$-agonist.

Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. Bethesda, MD, 2007. http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm

		Guide to rates of breathing in awake children:		
		Age	Normal Rate	
		< 2 months	< 60/minute	
		2–12 months	< 50/minute	
		1–5 years	< 40/minute	
		6–8 years	< 30/minute	
Use of accessory muscles; suprasternal retractions	Usually not	Commonly	Usually	Paradoxical thoracoabdominal movement
Wheeze	Moderate, often only	Loud; through	Usually loud;	Absence of wheeze

	and expiratory	out exhalation	throughout inhalation and exhalation	
Pulse/minute	< 100	100–120	> 120	Bradycardia
		Guide to normal pulse rates in children:		
		2–12 months	< 160/minute	
		1–2 years	< 120/minute	
		2–8 years	< 110/minute	
Pulsus paradoxus	Absent < 10 mm Hg	May be present 10–25 mm Hg	Often present > 25 mm Hg (adult)	Absence suggests respiratory muscle fatigue
			20–40	

			mm Hg (child)	
Functional Assessment				
PEF	70%	Approx. 40-69% or response lasts < 2 hours	< 40%	< 25%
Percent predicted or percent personal best				Note: PEF testing may not be needed in very severe attacks
PaO_2 (on air)	Normal (test not usually necessary)	60 mm Hg (test not usually necessary)	< 60 mm Hg: possible cyanosis	
and/or PCO_2	< 42 mm Hg (test not usually necessary)	< 42 mm Hg (test not usually necessary)	42 mm Hg: possible respiratory failure	
SaO_2 percent (on air) at	> 95% (test not usually necessary)	90-95% (test not usually	< 90%	

sea level	Hypercapnia (hypoventilation) develops more readily in young children than in adults and adolescents.	necessary)		

PEF, peak expiratory low; SaO_2, oxygen saturation.

Notes:

- The presence of several parameters, but not necessarily all, indicates the general classification of the exacerbation.
- Many of these parameters have not been systematically studied, especially as they correlate with each other. Thus, they serve only as general guides.
- The emotional impact of asthma symptoms on the patient and family is variable but must be recognized and addressed and can affect approaches to treatment and follow-up.

Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the

Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. Bethesda, MD, 2007. http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm

Symptoms and Signs

Asthma is characterized by episodic wheezing, difficulty in breathing, chest tightness, and cough. Excess sputum production is common. The frequency of asthma symptoms is highly variable. Some patients have infrequent, brief attacks of asthma while others may suffer nearly continuous symptoms. Asthma symptoms may occur spontaneously or may be precipitated or exacerbated by many different triggers as discussed above. Asthma symptoms are frequently worse at night; circadian variations in bronchomotor tone and bronchial reactivity reach their nadir between 3 AM and 4 AM, increasing symptoms of bronchoconstriction.

Some physical examination findings increase the probability of asthma. Nasal mucosal swelling, increased nasal secretions, and nasal polyps are often seen in patients with allergic asthma. Eczema, atopic dermatitis, or other manifestations of allergic skin disorders may also be present. Wheezing during normal breathing or a prolonged forced expiratory phase correlates well with the presence of airflow obstruction. Wheezing during forced expiration does not. Chest examination may be normal between exacerbations in patients with mild asthma. During severe asthma exacerbations, airflow may be too limited to produce wheezing, and the only diagnostic clue on auscultation may be globally reduced breath sounds with prolonged expiration . Hunched shoulders and use of accessory muscles of respiration suggest an increased work of breathing.

Pulmonary Function Testing

Clinicians are able to identify airflow obstruction on examination, but they have limited ability to assess it or to predict whether it is reversible. The evaluation for asthma should therefore include spirometry (FEV_1, FVC, FEV_1/FVC) before and after the administration of a short-acting bronchodilator (see illustration). These measurements help determine the presence and extent of airflow obstruction and whether it is immediately reversible. Airflow obstruction is indicated by a reduced FEV_1/FVC ratio. Significant reversibility of airflow obstruction is defined by an increase of 12% and 200 mL in FEV_1 or 15% and 200 mL in FVC after inhaling a short-acting bronchodilator. A positive bronchodilator response strongly confirms the diagnosis of asthma but a lack of responsiveness in the pulmonary function laboratory does not preclude success in a clinical trial of bronchodilator therapy. Severe airflow obstruction results in significant air trapping, with an increase in residual volume and consequent reduction in FVC, resulting in a pattern that suggests a restrictive ventilatory defect.

Fig.

Representative spirograms (upper panel) and expiratory flow-volume curves (lower panel) for normal *(A)*, obstructive *(B)*, and restrictive *(C)* patterns.

Bronchial provocation testing with inhaled histamine or methacholine may be useful when asthma is suspected but spirometry is nondiagnostic. Bronchial provocation is not recommended if the FEV_1 is less than 65% of predicted.

A positive methacholine test is defined as a 20% fall in the FEV_1 at exposure to a concentration of 8 mg/mL or less. A negative test has a negative predictive value for asthma of 95%. Exercise challenge testing may be useful in patients with symptoms of exercise-induced bronchospasm.

Arterial blood gas measurements may be normal during a mild asthma exacerbation, but respiratory alkalosis and an increase in the alveolar-arterial oxygen difference (A–a–DO_2) are common. During severe exacerbations, hypoxemia develops and the $PaCO_2$ returns to normal. The combination of an increased $PaCO_2$ and respiratory acidosis may indicate impending respiratory failure and the need for mechanical ventilation.

Peak expiratory flow (PEF) meters are handheld devices designed as personal monitoring tools. PEF monitoring can establish peak flow variability, quantify asthma severity, and provide both the patient and the clinician with objective measurements on which to base treatment decisions. There are conflicting data about whether measuring PEF improves asthma outcomes, but doing so is recommended to help confirm the diagnosis of asthma, to improve asthma control in patients with poor perception of airflow obstruction, and to identify environmental and occupational causes of symptoms. Predicted values for PEF vary with age, height, and gender but are poorly standardized. Comparison with reference values is less helpful than comparison with the patient's own baseline. PEF shows diurnal variation. It is generally lowest on first awakening and highest several hours before the midpoint of the waking day. PEF should be measured in the morning before the administration of a bronchodilator and in the afternoon after taking a bronchodilator. A 20% change in PEF values from morning to afternoon or from day to day suggests inadequately controlled asthma. PEF values less than 200 L/min indicate severe airflow obstruction.

Additional Testing

Routine chest radiographs in patients with asthma are usually normal or show only hyperinflation. Other findings may include bronchial wall thickening and diminished peripheral lung vascular shadows. Chest imaging is indicated when pneumonia, another disorder mimicking asthma, or a complication of asthma such as pneumothorax is suspected.

Skin testing or in vitro testing to assess sensitivity to environmental allergens can identify atopy in patients with persistent asthma who may benefit from therapies directed at their allergic diathesis. Evaluations for paranasal sinus disease or gastroesophageal reflux should be considered in patients with pertinent symptoms and in asthmatics with severe or refractory symptoms.

Noninvasive assessment of underlying airway inflammation through measurement of eosinophilia in induced sputum, or fractional nitric oxide concentration in exhaled breath condensates (FeNO), offers the promise of improved diagnosis and treatment strategies. Adjusting corticosteroid dose to minimize sputum eosinophilia appears to reduce the frequency of exacerbations compared with conventional clinical management, but the data are conflicting regarding the impact of FeNO on asthma outcomes. This is an exciting and rapidly changing area of asthma care.

Complications

Complications of asthma include exhaustion, dehydration, airway infection, and tussive syncope. Pneumothorax occurs but is rare. Acute hypercapnic and hypoxic respiratory failure occurs in severe disease.

Differential Diagnosis

It is prudent to consider conditions that mimic asthma in patients who have atypical symptoms or poor response to therapy. These disorders typically fall into one of four categories: upper airway disorders, lower airway disorders, systemic vasculitides, and psychiatric disorders. Upper airway disorders that mimic asthma include vocal fold paralysis, vocal fold dysfunction syndrome, foreign body aspiration, laryngotracheal masses, tracheal narrowing, tracheomalacia, and airway edema as in the setting of angioedema or inhalation injury. Lower airway disorders include nonasthmatic COPD (chronic bronchitis or emphysema), bronchiectasis, allergic bronchopulmonary mycosis, cystic fibrosis, eosinophilic pneumonia, and bronchiolitis obliterans. Systemic vasculitides with pulmonary involvement may have an asthmatic component, such as Churg-Strauss syndrome. Psychiatric causes include conversion disorders, which have been variably referred to as functional asthma, emotional laryngeal wheezing, vocal fold dysfunction, or episodic laryngeal dyskinesis. Münchausen syndrome or malingering may rarely explain a patient's complaints.

NAEPP 3 Diagnosis & Management Guidelines

The National Asthma Education and Prevention Program (NAEPP), in conjunction with the Global Initiative for Asthma (GINA), a collaboration between the National Institutes of Health (NIH)/National Heart, Lung, and Blood Institute (NHLBI) and the World Health Organization (WHO), recently released its third Expert Panel Report providing guidelines for diagnosis and management of asthma (NAEPP 3). This report identifies four components of chronic asthma diagnosis and management: (1) assessing and monitoring asthma severity and asthma control, (2) patient education designed to foster a partnership for care, (3) control of environmental factors and comorbid conditions that affect asthma, and (4) pharmacologic agents for asthma.

Assessing and monitoring asthma severity and asthma control

Severity is the intrinsic intensity of the disease process. Control is the degree to which symptoms and limitations on activity are minimized by therapy. Responsiveness is the ease with which control is achieved with therapy. NAEPP 3 guidelines now emphasize control over classifications of severity, since the latter is variable over time and in response to therapy. A measure of severity on initial presentation (see Figure 9–1) is helpful, however, in guiding the initiation of therapy. Control of asthma is assessed in terms of **impairment** (frequency and intensity of symptoms and functional limitations) and **risk** (the likelihood of acute exacerbations or chronic decline in lung function). A key insight is that these two domains of control may respond differently to treatment: some patients may have minimal impairment yet remain at risk for severe exacerbations, for example, in the setting of an upper respiratory tract infection. Table 9–1 is used to assess the adequacy of asthma control and is used in conjunction with Figure 9–2 to guide adjustments in therapy based on the level of control.

Figure 9–2.

Stepwise approach to managing asthma.

(Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. Bethesda, MD, 2007. http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm)

Patient education designed to foster a partnership for care

Active self-management reduces urgent care visits and hospitalizations and improves perceived control of asthma. Therefore, an outpatient preventive approach that includes self-management education is an integral part of effective asthma care. All patients, but particularly those with poorly controlled symptoms or a history of severe exacerbations, should have a written asthma action plan that includes instructions for daily management and measures to take in response to specific changes in status. Patients should be taught to recognize symptoms—especially patterns indicating inadequate asthma control or predicting the need for additional therapy.

Control of environmental factors and comorbid conditions that affect asthma

Significant reduction in exposure to nonspecific airway irritants or to inhaled allergens in atopic patients may reduce symptoms as well as medication needs. Comorbid conditions that impair asthma management, such as rhinosinusitis, gastroesophageal reflux, obesity, and obstructive sleep apnea, should be identified and treated. This search for complicating conditions is particularly crucial in the initial evaluation of a new diagnosis, and in patients whose asthma is difficult to control or subject to frequent exacerbations.

Pharmacologic agents for asthma

Asthma medications can be divided into two categories:

quick-relief (**reliever**) medications that act principally by direct relaxation of bronchial smooth muscle, thereby promoting prompt reversal of acute airflow obstruction to relieve accompanying symptoms, and long-term control (**controller**) medications that act primarily to attenuate airway inflammation and are taken daily independent of symptoms to achieve and maintain control of persistent asthma. NAEPP 3 recommendations emphasize daily anti-inflammatory therapy with inhaled corticosteroids as the cornerstone of treatment of persistent asthma.

Most asthma medications are administered orally or by inhalation. Inhalation of an appropriate agent results in a more rapid onset of pulmonary effects as well as fewer systemic effects compared with oral administration of the same dose. Metered-dose inhalers (MDIs) propelled by chlorofluorocarbons (CFCs) have been the most widely used delivery system, but non-CFC propellant systems such as hydrofluoroalkane (HFA), and dry powder inhalers (DPIs) are increasingly available. Proper MDI technique and the use of an inhalation chamber improve drug delivery to the lung and decrease oropharyngeal deposition. Nebulizer therapy is reserved for acutely ill patients and those who cannot use MDIs because of difficulties with coordination or cooperation.

Treatment

The goals of asthma therapy are to minimize chronic symptoms that interfere with normal activity (including exercise), to prevent recurrent exacerbations, to reduce or eliminate the need for emergency department visits or hospitalizations, and to maintain normal or near-normal pulmonary function. These goals should be met while providing pharmacotherapy with the fewest adverse effects and while meeting patients' and families' expectations of satisfaction with asthma care.

Long-Term Control Medications

Anti-inflammatory agents, long-acting bronchodilators, and leukotriene modifiers comprise the important long-term control medications (Tables 9–4 and 9–5). Other classes of agents are mentioned briefly below.

Table 9–4. Long-term control medications for asthma.

Medication	**Dosage Form**	**Adult Dose**	**Comments**
Inhaled Corticosteroids			
Systemic Corticosteroids			**(Applies to all three corticosteroids)**
Methylprednisolone	2, 4, 6, 8, 16, 32 mg	7.5-60 mg daily in a	For long-

	tablets	single dose in AM or every other day as needed for control	term treatment of severe persistent asthma, administer single dose in a.m. either daily or on alternate days (alternate-day therapy may produce less adrenal suppression). Short courses or "bursts" are effective for establishing control when initiating therapy or during a period of gradual deterioration.
Prednisolone	5 mg tablets, 5 mg/5 mL, 15 mg/5 mL	Short-course "burst": to achieve control, 40-60 mg per day as single or 2 divided doses for 3-10 days	
Prednisone	1, 2.5, 5, 10, 20, 50 mg tablets;		There is no evidence that tapering the

	5 mg/mL, 5 mg/mL		dose following improvement in symptom control and pulmonary function prevents relapse.
Inhaled Long-Acting $_2$-Agonists			**Should not be used for symptom relief or exacerbations. Use with inhaled corticosteroids.**
Salmeterol	DPI 50 mcg/blister	1 blister every 12 hors	Decreased duration of protection against EIB may occur with regular use.
			Decreased duration of protection

			against EIB may occur with regular use.
Formoterol	DPI 12 mcg/single-use capsule	1 capsule every 12 hours	Each capsule is for single use only; additional doses should not be administered for at least 12 hours.
			Capsules should be used only with the Aerolizor™ inhaler and should not be taken orally.
Combined Medication			
Fluticasone/Salmeterol	DPI	1 inhalation twice daily; dose depends	100/50 DPI or 45/21 HFA for patient not controlled on low- to
	100 mcg/50 mcg,		
	250		

	mcg/50 mcg, or	on severity of asthma	medium-dose inhaled corticosteroids
	500 mcg/50 mcg		
	HFA		250/50 DPI or 115/21 HFA for patients not controlled on medium- to high-dose inhaled corticosteroids
	45 mcg/21 mcg		
	115 mcg/21 mcg		
	230 mcg/21 mcg		
Budesonide/Formoterol	HFA MDI	2 inhalations twice daily; dose depends on severity of asthma	80/4.5 for patients who have asthma not controlled on low- to medium-dose inhaled corticosteroids
	80 mcg/4.5 mcg		160/4.5 for patients who

	160 mcg/4.5 mcg		have asthma not controlled on medium- to high-dose inhaled corticosteroids
Cromolyn and Nedocromil			
Cromolyn	MDI 0.8 mg/puff	2 puffs four times daily	4–6 week trial may be needed to determine maximum benefit.
	Nebulizer 20 mg/ampule	1 ampule four times daily	Dose by MDI may be inadequate to affect hyperresponsiveness.
Nedocromil	MDI	2 puffs four times daily	One dose before exercise or allergen exposure provides effective prophylaxis for

			1-2 hours. Not as effective for EIB as SABA.
	1.75 mg/puff		Once control is achieved, the frequency of dosing may be reduced.
Leukotriene Modifiers			
Leukotriene Receptor Antagonists			
Montelukast	4 mg or 5 mg chewable tablet	10 mg each night at bedtime	Montelukast exhibits a flat dose-response curve. Doses > 10 mg will not produce a greater response in adults.
	10 mg tablet		
Zafirlukast	10 or 20 mg tablet	40 mg daily (20 mg tablet twice daily)	For zafirlukast, administration with meals decreases

			bioavailability; take at least one hour before or 2 hours after meals. Monitor for symptoms and signs of hepatic dysfunction.
5-Lipoxygenase inhibitor			
Zileuton	600 mg tablet	2400 mg daily (600 mg four times daily)	For zileuton, monitor hepatic enzymes (ALT).
Methylxanthines			
Theophylline	Liquids, sustained-release tablets, and capsules	Starting dose 10 mg/kg/d up to 300 mg maximum; usual maximum dose 800	Adjust dosage to achieve serum concentration of 5-15 mcg/mL at steady-state (at least 48 hours on same

		mg/d	dosage).
			Due to wide interpatient variability in theophylline metabolic clearance, routine serum theophylline level monitoring is important.
			See below for factors that can affect theophylline levels.
Immunomodulators			
Omalizumab	Subcutaneous injection, 150 mg/1.2 mL following reconstitution with	150–375 mg SC every 2–4 weeks, depending on body weight and pretreatme	Do not administer more than 150 mg per injection site. Monitor for anaphylaxis for

	1.4 mL sterile water for injection	nt serum IgE level	2 hours following at least the first 3 injections.

Factor[1,2]	Decreases Theophylline Concentrations	Increases Theophylline Concentrations	Recommended Action
Food	or delays absorption of some sustained-release theophylline (SRT) products	rate of absorption (fatty foods)	Select theophylline preparation that is not affected by food.
Diet	metabolism (high protein)	metabolism (high carbohydrate)	Inform patients that major changes in diet are not recommended while taking theophylline.
Systemic, febrile			Decrease

viral illness (eg, influenza)		metabolism	theophylline dose according to serum concentration. Decrease dose by 50% if serum concentration measurement is not available.
Hypoxia, cor pulmonale, and decompensated congestive heart failure, cirrhosis		metabolism	Decrease dose according to serum concentration.
Age	metabolism (1–9 years)	metabolism (< 6 months, elderly)	Adjust dose according to serum concentration.
Phenobarbital, phenytoin, carbamazepine	metabolism		Increase dose according to serum concentration.
Cimetidine		metabolis	Use alternative H_2

		m	blocker (eg, famotidine or ranitidine).
Macrolides: erythromycin, clarithromycin		metabolism	Use alternative macrolide antibiotic, azithromycin, or alternative antibiotic or adjust theophylline dose.
Quinolones: ciprofloxacin, enoxacin, pefloxacin		metabolism	Use alternative antibiotic or adjust theophylline dose. Circumvent with ofloxacin if quinolone therapy is required.
Rifampin			Increase

	metabolism		dose according to serum concentration.
Ticlopidine		metabolism	Decrease dose according to serum concentration.
Smoking	metabolism		Advise patient to stop smoking; increase dose according to serum concentration.

[1] Factors affecting serum theophylline concentration.

[2] This list is not all inclusive; for discussion of other factors, see package inserts.

DPI, dry powder inhaler; EIB, exercise-induced bronchospasm; HFA, hydrofluoroalkane; IgE, immunoglobulin E; MDI, metered-dose inhaler; SABA, short-acting $_2$-agonist.

Table 9–5. Estimated comparative daily dosages for inhaled corticosteroids for asthma

Drug	**Low Daily Dose Adult**	**Medium Daily Dose Adult**	**High Daily Dose Adult**
Beclomethasone HFA	80–240 mcg	>240–480 mcg	>480 mcg
40 or 80 mcg/puff			
Budesonide DPI	180–600 mcg	>600–1200 mcg	>1200 mcg
90, 180, or 200 mcg/inhalation			
Flunisolide	500–1000 mcg	>1000–2000 mcg	>2000 mcg
250 mcg/puff			
Flunisolide HFA	320 mcg	>320–640 mcg	>640 mcg
80 mcg/puff			
Fluticasone			
HFA/MDI: 44, 110, or 220 mcg/puff	88–264 mcg	>264–440 mcg	>440 mcg

DPI: 50, 100, or 250 mcg/inhalation	100–300 mcg	>300–500 mcg	>500 mcg
Mometasone DPI	200 mcg	400 mcg	>400 mcg
200 mcg/puff			
Triamcinolone acetonide	300–750 mcg	>750–1500 mcg	>1500 mcg
75 mcg/puff			

DPI, dry power inhaler; HFA, hydrofluoroalkaline; MDI, metered-dose inhaler.

Notes:

- **The most important determinant of appropriate dosing is the clinician's judgment of the patient's response to therapy.** The clinician must monitor the patient's response on several clinical parameters and adjust the dose accordingly. The stepwise approach to therapy emphasizes that once control of asthma is achieved, the dose of medication should be carefully titrated to the minimum dose required to maintain control, thus reducing the potential for adverse effect.
- Some doses may be outside packaging labeling, especially in the high-dose range.
- MDI dosages are expressed as the actuator dose (the amount of drug leaving the actuator and delivered to the patient), which is the labeling required in the

United States. This is different from the dosage expressed as the valve dose (the amount of drug leaving the valve, not all of which is available to the patient), which is used in many European countries and in some scientific literature. DPI doses are expressed as the amount of drug in the inhaler following activation.

- Comparative dosages are based on published comparative clinical trials. The rationale for some key comparisons is summarized as follows:

—The high dose is the dose that appears likely to be the threshold beyond which significant hypothalamic-pituitary adrenal (HPA) axis suppression is produced, and, by extrapolation, the risk is increased for other clinically significant systemic effects if used for prolonged periods of time.

—The low- and medium-doses reflect findings from dose-ranging studies in which incremental efficacy within the low- to medium-dose ranges was established without increased systemic effect as measured by overnight cortisol excretion. The studies demonstrated a relatively flat-dose response curve for efficacy at the medium-dose range; that is, increasing the dose of high-dose range did not significantly increase efficacy but did increase systemic effect.

—The dose for budesonide DPI is based on recently

available comparative data with other medications. These new data, including meta-analyses, show that budesonide DPI is comparable to approximately twice the microgram dose of fluticasone MDI or DPI.
—The dose for beclomethasone in HFA inhaler should be approximately one-half the dose for beclomethasone in chlorofluorocarbon (CFC) inhaler for adults and children, based on studies demonstrating that the different pharmaceutical properties of the medications result in enhanced lung delivery for the HFA (a less forceful spray from the HFA propellant and a reengineered nozzle that allows a smaller particle size) and clinical trials demonstrating similar potency to fluticasone at 1:1 dose ratio.
—The dose for mometasone DPI is based on product information and current literature. Mometasone is approved for once daily administration. Mometasone furoate by dry powder achieved effects similar to twice the dose of budesonide by dry powder and comparable to a slightly higher dose of fluticasone propionate by dry powder.
—The dose for flunisolide HFA is based on product information and current literature.

- **Bioavailability** Both the relative potency and the relative bioavailability (systemic availability) determine the potential for systemic activity of an inhaled corticosteroid preparation. As illustrated here, the bioavailability of an inhaled corticosteroid is dependent on the absorption of the dose delivered to the lungs and the oral bioavailability of the swallowed portion of the dose received.

—Absorption of the dose delivered to the lungs:

- Approximately 10–50% of the dose from the MDI is delivered to the lungs. This amount varies among preparations and delivery devices.
- Nearly all of the amount delivered to the lungs is bioavailable.

—Oral bioavailability of the swallowed portion of the dose received:

- Approximately 50–80% of the dose from the MDI without a spacer/holding chamber is swallowed.
- The oral bioavailability of this amount varies:

Either a high first-pass metabolism or the use of a spacer/holding chamber with an MDI can decrease oral bioavailability, thus enhancing safety.
The approximate oral bioavailability of inhaled corticosteroids has been reported as: beclomethasone dipropionate 20% flunisolide, 21%; triamcinolone acetonide, 10.6%; budesonide, 11%; fluticasone

propionate, 1%; mometasone, <1%.

- **Potential drug interactions** A number of the inhaled corticosteroids, including fluticasone, budesonide, and mometasone, are metabolized in the gastrointestinal tract and liver by CYP 3A4 isoenzymes. Potent inhibitors of CYP 3A4, such as ritonavir and ketoconazole, have the potential for increasing systemic concentrations of these inhaled corticosteroids by increasing oral availability and decreasing systemic clearance. Some cases of clinically significant Cushing syndrome and secondary adrenal insufficiency have been reported (Johnson et al. 2006; Samaras et al. 2005).

http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm

Anti-inflammatory agents

Corticosteroids are the most potent and consistently effective anti-inflammatory agents currently available. They reduce both acute and chronic inflammation, resulting in fewer asthma symptoms, improvement in airflow, decreased airway hyper-responsiveness, and fewer asthma exacerbations. These agents may also potentiate the action of -adrenergic agonists.

Inhaled corticosteroids are preferred, first-line agents for all patients with persistent asthma. Patients with persistent symptoms or asthma exacerbations who are not taking inhaled corticosteroids should be started on an inhaled corticosteroid. The most important determinants of agent selection and appropriate dosing are the patient's status and response to treatment. Dosages for inhaled corticosteroids vary depending on the specific agent and delivery device. For most patients, twice-daily dosing provides adequate control of asthma. Once-daily dosing may be sufficient in selected patients. Maximum responses from inhaled corticosteroids may not be observed for months. The use of an inhalation chamber coupled with mouth washing after MDI use decreases local side effects (cough, dysphonia, oropharyngeal candidiasis) and systemic absorption. DPIs are not used with an inhalation chamber. Systemic effects (adrenal suppression, osteoporosis, skin thinning, easy bruising, and cataracts) may occur with high-dose inhaled corticosteroid therapy.

Systemic corticosteroids (oral or parenteral) are most effective in achieving prompt control of asthma during exacerbations or when initiating long-term asthma therapy in patients with severe symptoms. In patients with refractory, poorly controlled asthma, systemic corticosteroids may be required for the long-term suppression of symptoms. Repeated efforts should be made to reduce the dose to the minimum needed to control symptoms. Alternate-day treatment is preferred to daily treatment. Rapid discontinuation of systemic corticosteroids after chronic use may precipitate adrenal insufficiency. Concurrent treatment with calcium supplements and vitamin D should be initiated to prevent corticosteroid-induced bone mineral loss in long-term administration. Bisphosphonates may offer additional protection to these patients.

Long-acting bronchodilators

Mediator inhibitors

Cromolyn sodium and nedocromil are long-term control medications that prevent asthma symptoms and improve airway function in patients with mild persistent asthma or exercise-induced symptoms. These agents modulate mast cell mediator release and eosinophil recruitment and inhibit both early and late asthmatic responses to allergen challenge and exercise-induced bronchospasm. They can be effective when taken before an exposure or exercise but do not relieve asthmatic symptoms once present. The clinical response to these agents is less predictable than the response to inhaled corticosteroids. Nedocromil may help reduce the dose requirements for inhaled corticosteroids. Both agents have excellent safety profiles.

-adrenergic agonists

Long-acting $_2$-agonists provide bronchodilation for up to 12 hours after a single dose. Salmeterol and formoterol are the two long-acting $_2$-agonists available in the United States. They are administered via dry powder delivery devices. They are indicated for long-term prevention of asthma symptoms, nocturnal symptoms, and for prevention of exercise-induced bronchospasm. When added to standard doses of inhaled corticosteroids, long-acting $_2$-agonists provide control equivalent to what is achieved by doubling the inhaled corticosteroid dose. Side effects are minimal at standard doses. Long-acting $_2$-agonists should not be used as monotherapy since they have no anti-inflammatory effect and since monotherapy with long-acting $_2$-agonists has been associated in two large studies with a small but statistically significant increased risk of severe or fatal asthma attacks. This increased risk may relate to genetic variation in the -adrenergic receptor, but it has not been fully explained and remains an area of controversy. The efficacy of combined inhaled corticosteroid and long-acting $_2$-agonist therapy has led to marketing of combination medications that deliver both agents simultaneously (see Table 9–4). Combination inhalers containing formoterol and budesonide have shown efficacy in both maintenance and rescue, given formoterol's short time to onset.

Phosphodiesterase inhibitors

Theophylline provides mild bronchodilation in asthmatic patients. This drug has modest anti-inflammatory properties, enhances mucociliary clearance, and strengthens diaphragmatic contractility. Sustained-release theophylline preparations are effective in controlling nocturnal asthma and are usually reserved for use as adjuvant therapy in patients with moderate or severe persistent asthma. Theophylline serum concentrations need to be monitored closely owing to the drug's narrow toxic-therapeutic range, individual differences in metabolism, and the effects of many factors on drug absorption and metabolism. Decreases in theophylline clearance accompany the use of cimetidine, macrolide and quinolone antibiotics, and oral contraceptives. Increases in theophylline clearance are caused by rifampin, phenytoin, barbiturates, and tobacco.

Adverse effects at therapeutic doses include insomnia, upset stomach, aggravation of dyspepsia and gastroesophageal reflux symptoms, and urination difficulties in elderly men with prostatism. Dose-related toxicities are common and include nausea, vomiting, tachyarrhythmias, headache, seizures, hyperglycemia and hypokalemia.

Leukotriene modifiers

Leukotrienes are potent biochemical mediators that contribute to airway obstruction and asthma symptoms by contracting airway smooth muscle, increasing vascular permeability and mucus secretion, and attracting and activating airway inflammatory cells. Zileuton is a 5-lipoxygenase inhibitor that decreases leukotriene production, and zafirlukast and montelukast are cysteinyl leukotriene receptor antagonists. They cause modest improvements in lung function and reductions in asthma symptoms and lessen the need for $_2$-agonist rescue therapy. These agents are alternatives to low-dose inhaled corticosteroids in patients with mild persistent asthma, although, as monotherapy, their effect is generally less than inhaled corticosteroids. Zileuton can cause reversible elevations in plasma aminotransferase levels, and Churg-Strauss syndrome has been diagnosed in a small number of patients who have taken montelukast or zafirlukast, although this is suspected to be an effect of corticosteroid withdrawal as opposed to a direct drug effect.

Desensitization

Immunotherapy for specific allergens may be considered in selected asthma patients who have exacerbations of asthma symptoms when exposed to allergens to which they are sensitive and who do not respond to environmental control measures or other forms of conventional therapy. Studies show a reduction in asthma symptoms in patients treated with single-allergen immunotherapy. Because of the risk of immunotherapy-induced bronchoconstriction, it should be administered only in a setting where such complications can be immediately treated.

Vaccination

Patients with asthma should receive pneumococcal vaccination (Pneumovax) and annual influenza vaccinations. Inactive vaccines (Pneumovax) are associated with few side effects but use of the live attenuated influenza vaccine intranasally may be associated with an increase in asthma exacerbations in young children.

Miscellaneous agents

Oral sustained-release $_2$-agonists are reserved for patients with bothersome nocturnal asthma symptoms or moderate to severe persistent asthma who do not respond to other therapies. Omalizumab is a recombinant antibody that binds IgE without activating mast cells. In clinical trials in moderate to severe asthmatic patients with elevated IgE levels, it reduces the need for corticosteroids.

Etanercept, a soluble TNF- receptor antagonist, has shown modest efficacy in one small study of severe asthma.

Quick-Relief Medications

Short-acting bronchodilators and systemic corticosteroids comprise the important medications in this group of agents (Table 9–6).

Table 9–6. Quick-relief medications for asthma.

Medication	**Dosage form**	**Adult dose**	**Comments**
Inhaled Short-Acting $_2$-Agonists			
	MDI		
Albuterol CFC	90 mcg/puff, 200 puffs/canister	2 puffs 5 minutes before exercise	• An increasing use or lack of expected effect indicates diminished control of asthma. • Not recommended for long-term daily treatment.
Albuterol HFA	90 mcg/puff, 200 puffs/canister	2 puffs every 4–6 hours as needed	
Pirbuterol CFC	200		

	mcg/puff, 400 puffs/canister		Regular use exceeding 2 days/week for symptom control (not prevention of EIB) indicates the need to step up therapy. • Differences in potency exist, but all products are essentially comparable on a per puff basis. • May double usual dose for mild exacerbations. • Should prime the inhaler by releasing
Levalbuterol HFA	45 mcg/puff, 200 puffs/canister		

			four actuations prior to use. - Periodically clean HFA activator, as drug may block/plug orifice. - Nonselective agents (ie epinephrine, isoproterenol, metaproterenol) are not recommended due to their potential for excessive cardiac stimulation, especially in high doses.
	Nebulizer solution		

Albuterol	0.63 mg/3 mL	1.25–5 mg in 3 mL of saline every 4–8 hours as needed	- May mix with budesonide inhalant suspension, cromolyn or ipratropium nebulizer solutions. May double dose for severe exacerbations.
	1.25 mg/3 mL		
	2.5 mg/3 mL		
	5 mg/mL (0.5%)		
Levalbuterol (R-albuterol)	0.31 mg/3 mL	0.63–1.25 mg every 8 hours as needed	- Compatible with budesonide inhalant suspension. The product is a sterile-filled, preservative-free, unit dose vial.
	0.63 mg/3 mL		
	1.25 mg/0.5 mL		
	1.25 mg/3 mL		
Anticholinergics			

	MDI		
Ipratropium HFA	17 mcg/puff, 200 puffs/canister	2–3 puffs every 6 hours	• Evidence is lacking for anticholinergics producing added benefit to $_2$-agonists in long-term control asthma therapy.
	Nebulizer solution		
	0.25 mg/mL (0.025%)	0.25 mg every 6 hours	
	MDI		
Ipratropium with albuterol	18 mcg/puff of ipratropium bromide	2–3 puffs every 6	

	and 90 mcg/puff of albuterol	hours	
	200 puffs/canister		
	Nebulizer solution		
	0.5 mg/3 mL ipratropium bromide and 2.5 mg/3 mL albuterol	3 mL every 4–6 hours	• Contains EDTA to prevent discolorations of the solution. This additive does not induce bronchospasm.
Systemic Corticosteroids			
Methylprednisolone	2, 4, 6, 8, 16, 32 mg tablets	Short course "burst": 40–60 mg/d	• Short courses or "bursts" are effective for establishing control when

		as single or 2 divided doses for 3–10 days	initiating therapy or during a period of gradual deterioration. • The burst should be continued until symptoms resolve and the PEF is at least 80% of personal best. This usually requires 3–10 days but may require longer. There is no evidence that tapering the dose following
Prednisolone	5 mg tablets, 5 mg/5 mL, 15 mg/5 mL		
Prednisone	1, 2.5, 5, 10, 20, 50 mg tablets; 5 mg/mL, 5 mg/5mL		

			improvements prevents relapse. • May be used in place of a short burst of oral corticosteroids in patients who are vomiting or if adherence is a problem.
	Repository injection		
(Methylprednisolone acetate)	40 mg/mL 80 mg/mL	240 mg IM once	

CFC, chlorofluorocarbon; EIB, exercise-induced bronchospasm; HFA, hydrofluoroalkane; IM, intramuscular; MDI, metered-dose inhaler; PEF, peak expiratory flow.

http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm

-Adrenergic agonists

Short-acting inhaled $_2$-agonists, including albuterol, levalbuterol, bitolterol, pirbuterol, and terbutaline, are the most effective bronchodilators during exacerbations. All patients with acute symptoms should take one of these agents. There is no convincing evidence to support the use of one agent over another. $_2$-Agonists relax airway smooth muscle and cause a prompt increase in airflow and reduction of symptoms. Administration before exercise effectively prevents exercise-induced bronchoconstriction. $_2$-Selective agents may produce less cardiac stimulation than those with mixed $_1$ and $_2$ activities, although clinical trials have not consistently demonstrated this finding.

Inhaled -adrenergic therapy is as effective as oral or parenteral therapy in relaxing airway smooth muscle and improving acute asthma and offers the advantages of rapid onset of action (< 5 minutes) with fewer systemic side effects. Repetitive administration produces incremental bronchodilation. Intravenous and subcutaneous routes of administration should be reserved for patients who because of age or mechanical factors are unable to inhale medications.

One or two inhalations of a short-acting inhaled $_2$-agonist from an MDI are usually sufficient for mild to moderate symptoms. Severe exacerbations frequently require higher doses: 6–12 puffs every 30–60 minutes of albuterol by MDI with an inhalation chamber or 2.5 mg by nebulizer provide equivalent bronchodilation. Administration by wet nebulization does not offer more effective delivery than MDIs but does provide higher doses. With most $_2$-agonists, the recommended dose by nebulizer for acute asthma (albuterol, 2.5 mg) is 25–30 times that delivered by a single activation of the MDI (albuterol, 0.09 mg). This difference suggests that standard dosing of inhalations from an MDI will often be insufficient in the setting of an acute exacerbation. Independent of dose, nebulizer therapy may be more effective in patients who are unable to coordinate inhalation of medication from an MDI because of age, agitation, or severity of the exacerbation.

Scheduled daily use of short-acting $_2$-agonists is not recommended. Increased use (more than one canister a month) or lack of expected effect indicates diminished asthma control and dictates the need for additional long-term control therapy.

Anticholinergics

Anticholinergic agents reverse vagally mediated bronchospasm but not allergen- or exercise-induced bronchospasm. They may decrease mucus gland hypersecretion seen in asthma. Ipratropium bromide, a quaternary derivative of atropine free of atropine's side effects, is less effective than $_2$-agonists for relief of acute bronchospasm, but it is the inhaled drug of choice for patients with intolerance to $_2$-agonists and with bronchospasm due to -blocker medications. Ipratropium bromide reduces the rate of hospital admissions when added to inhaled short-acting $_2$-agonists in patients with moderate to severe asthma exacerbations. The role of anticholinergic agents in long-term management of asthma has not been clarified.

Phosphodiesterase inhibitors

Methylxanthines are not recommended for therapy of asthma exacerbations. Aminophylline has clearly been shown to be less effective than $_2$-agonists when used as single-drug therapy for acute asthma and adds little except toxicity to the acute bronchodilator effects achieved by nebulized metaproterenol alone. Patients with exacerbations who are currently taking a theophylline-containing preparation should have their serum theophylline concentration measured to exclude theophylline toxicity.

Corticosteroids

Systemic corticosteroids are effective primary treatment for patients with moderate to severe asthma exacerbations and for patients with exacerbations who do not respond promptly and completely to inhaled $_2$-agonist therapy. These medications speed the resolution of airflow obstruction and reduce the rate of relapse. Delays in administering corticosteroids may result in delayed benefits from these important agents. Therefore, oral corticosteroids should be available for early administration at home in many patients with moderate to severe asthma. The minimal effective dose of systemic corticosteroids for asthma patients has not been identified. Outpatient prednisone "burst" therapy is 0.5–1 mg/kg/d (typically 40–60 mg) as a single or in two divided doses for 3–10 days. Severe exacerbations requiring hospitalization typically require 1 mg/kg of prednisone equivalent every 6–12 hours for 48 hours or until the FEV_1 (or PEF rate) returns to 50% of predicted (or 50% of baseline). The dose is then decreased to 60–80 mg/d until the PEF reaches 70% of predicted or personal best. No clear advantage has been found for higher doses of corticosteroids in severe exacerbations. It may be prudent to administer corticosteroids to critically ill patients via the intravenous route in order to avoid concerns about altered gastrointestinal absorption.

Antimicrobials

Empiric antibiotics are not recommended in routine asthma exacerbations, although antibiotics that cover atypical organisms (eg, telithromycin) are an area of ongoing research. Antibiotics may be useful if bacterial respiratory tract infections are thought to contribute. Thus, patients with fever or purulent sputum and evidence of pneumonia or bacterial sinusitis are reasonable candidates for such therapy.

Treatment of Asthma Exacerbations

NAEPP 3 asthma treatment algorithms begin with an assessment of the severity of a patient's baseline asthma. Adjustments to that algorithm follow a stepwise approach based on a careful assessment of asthma control. Most instances of uncontrolled asthma are mild and can be managed successfully by patients at home with the telephone assistance of a clinician (Figure 9–3).

Figure 9–3.

Management of asthma exacerbations: home treatment. (Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. Bethesda, MD, 2007. http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm)

More severe exacerbations require evaluation and management in an urgent care or emergency department setting (Figure 9–4).

Figure 9–4.

Management of asthma exacerbations: emergency department and hospital-based treatment. (Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. Bethesda, MD, 2007. http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm)

Mild Exacerbations

Mild asthma exacerbations are characterized by only minor changes in airway function (PEF > 80%) and minimal symptoms and signs of airway dysfunction (see Tables 9–2 and 9–3). The majority of such exacerbations can be managed at home with the telephone assistance of a clinician. Many patients respond quickly and fully to an inhaled short-acting $_2$-agonist alone. However, an inhaled short-acting $_2$-agonist may need to be continued at increased doses, eg, every 3–4 hours for 24–48 hours. In patients not taking an inhaled corticosteroid, initiation of this agent should be considered.

In patients already taking an inhaled corticosteroid, a 7-day course of oral corticosteroids (0.5–1.0 mg/kg/d) may be necessary. Doubling the dose of inhaled corticosteroid is not effective and is not recommended in the NAEPP 3 guidelines.

Moderate Exacerbations

The principal goals of treatment of moderate asthma exacerbations are correction of hypoxemia, reversal of airflow obstruction, and reduction of the likelihood of recurrence of obstruction. Early intervention may lessen the severity and shorten the duration of an exacerbation. Of paramount importance is correction of hypoxemia through the use of supplemental oxygen. Airflow obstruction is treated with continuous administration of an inhaled short-acting $_2$-agonist and the early administration of systemic corticosteroids. Serial measurements of lung function to quantify the severity of airflow obstruction and its response to treatment are useful. The improvement in FEV_1 after 30 minutes of treatment correlates significantly with a broad range of indices of the severity of asthma exacerbations. Serial measurement of airflow in the emergency department is an important factor in disposition and may reduce the rate of hospital admissions for asthma exacerbations. The post-exacerbation care plan is an important aspect of management. Regardless of the severity, all patients should be provided with necessary medications and education in how to use them, instruction in self-assessment, a follow-up appointment, and instruction in an action plan for managing recurrence.

Severe Exacerbations

Owing to the life-threatening nature of severe exacerbations of asthma, treatment should be started immediately once the exacerbation is recognized. All patients with a severe exacerbation should immediately receive oxygen, high doses of an inhaled short-acting $_2$-agonist, and systemic corticosteroids. A brief history pertinent to the exacerbation can be completed while treatment is being initiated. More detailed assessments, including laboratory studies, usually add little in the early phase of evaluation and management and should be postponed until after therapy is instituted.

Asphyxia is a common cause of fatal asthma, and oxygen therapy is therefore very important. Supplemental oxygen should be given to maintain an $SaO_2 > 90\%$ or a $PaO_2 >$ 60 mm Hg. Oxygen-induced hypoventilation is extremely rare, and concern for hypercapnia should never delay correction of hypoxemia.

Frequent high-dose delivery of an inhaled short-acting $_2$-agonist is indicated and is usually well tolerated in the setting of severe airway obstruction. Some studies suggest that continuous therapy is more efficacious than intermittent administration of these agents, but there is no clear consensus as long as similar doses are administered. At least three MDI or nebulizer treatments should be given in the first hour of therapy. Thereafter, the frequency of administration varies according to the improvement in airflow and associated symptoms and the occurrence of side effects. Ipratropium bromide reduces the rate of hospital admissions when added to inhaled short-acting $_2$-agonists in patients with moderate to severe asthma exacerbations.

Systemic corticosteroids are administered as detailed above. Mucolytic agents (eg, acetylcysteine, potassium iodide) may worsen cough or airflow obstruction.

Anxiolytic and hypnotic drugs are generally contraindicated in severe asthma exacerbations because of their respiratory depressant effects. In acute severe asthma ($FEV_1 < 25\%$ of predicted on presentation, or failure to respond to initial treatment), intravenous magnesium sulfate (2 g intravenously over 20 minutes) produces a detectable improvement in airflow and may reduce hospitalization rates.

Repeat assessment of patients with severe exacerbations should be made after the initial dose of inhaled bronchodilator and after three doses of inhaled bronchodilators (60–90 minutes after initiating treatment). The response to initial treatment is a better predictor of the need for hospitalization than is the severity of an exacerbation on presentation. The decision to hospitalize a patient should be based on the duration and severity of symptoms, severity of airflow obstruction, course and severity of prior exacerbations, medication use at the time of the exacerbation, access to medical care and medications, adequacy of social support and home conditions, and presence of psychiatric illness. In general, discharge to home is appropriate if the PEF or FEV_1 has returned to 60% of predicted or personal best and symptoms are minimal or absent. Patients with a rapid response to treatment should be observed for 30 minutes after the most recent dose of bronchodilator to ensure stability of response before discharge to home.

A small subset of patients will not respond well to treatment and will show signs of impending respiratory failure due to a combination of worsening airflow obstruction and respiratory muscle fatigue (Table 9–3). Such patients can deteriorate rapidly and thus should be monitored in a critical care setting. Intubation of an acutely ill asthma patient is technically difficult and is best done semi-electively, before the crisis of a respiratory arrest. At the time of intubation, close attention should be given to maintaining intravascular volume because hypotension commonly accompanies the administration of sedation and the initiation of positive-pressure ventilation in patients dehydrated due to poor recent oral intake and high insensible losses.

The main goals of mechanical ventilation are to ensure adequate oxygen and to avoid barotrauma. Controlled hypoventilation with permissive hypercapnia is often required to limit airway pressures. Frequent high-dose delivery of inhaled short-acting ${}_2$-agonists should be continued along with anti-inflammatory agents as discussed above. Many questions remain regarding the optimal delivery of inhaled ${}_2$-agonists to intubated, mechanically ventilated patients. Further studies are needed to determine the comparative efficacy of MDIs and nebulizers, optimal ventilator settings to use during drug delivery, ideal site along the ventilator circuit for introduction of the delivery system, and maximal acceptable drug doses. In acute severe asthma ($FEV_1 <$ 25% of predicted), intravenous magnesium sulfate produces a detectable but clinically insignificant improvement in airflow. Unconventional therapies such as helium-oxygen mixtures and inhalational anesthetic agents are of unclear benefit but may be appropriate in selected patients.

When to Refer

- Atypical presentation or uncertain diagnosis, particularly if additional diagnostic testing is required (bronchoprovocation challenge, skin testing for allergies, rhinoscopy, consideration of occupational exposure).
- Complicating comorbid problems, such as rhinosinusitis, tobacco use, multiple environmental allergies, suspected allergic bronchopulmonary aspergillosis.
- Suboptimal response to therapy.
- Patient is not meeting goals of asthma therapy after 3–6 months of treatment.
- Adult patient requires high-dose inhaled corticosteroids for control.
- Patient has required more than two courses of oral prednisone therapy in the past 12 months.
- Patient has an exacerbation requiring hospitalization in the past 12 months.

- Patient has had a life-threatening asthma exacerbation.
- Presence of social or psychological issues interfering with asthma management.

Chronic Obstructive Pulmonary Disease

Essentials of Diagnosis

- History of cigarette smoking.
- Chronic cough, dyspnea (in emphysema), and sputum production (in chronic bronchitis).
- Rhonchi, decreased intensity of breath sounds, and prolonged expiration on physical examination ; .
- Airflow limitation on pulmonary function testing that is not fully reversible and most often progressive (see illustration).

Audio
Breath sound from a patient with severe long-term chronic obstructive lung disease. The patient was in respiratory distress because of a cyst on his larynx, causing stridor. The stridor can be distinguished by the inspiratory extenuation of the higher-pitched continuous noise. (Reproduced, with permission, from "Self-Assessment on Sounds of the Chest," narrated by

Raymond Murphy, Jr., MD [vinyl record distributed by ACCP at 43rd Annual Scientific Assembly, Las Vegas, 1977].)

General Considerations

COPD is a disease state characterized by the presence of airflow obstruction due to chronic bronchitis or emphysema; the airflow obstruction is generally progressive, may be accompanied by airway hyperreactivity, and may be partially reversible (American Thoracic Society). The NHLBI estimates that 14 million Americans have been diagnosed with COPD; an equal number are thought to be afflicted but remain undiagnosed. Grouped together, COPD and asthma now represent the fourth leading cause of death in the United States, with over 120,000 deaths reported annually. The death rate from COPD is increasing rapidly, especially among elderly men.

Most patients with COPD have features of both emphysema and chronic bronchitis. **Chronic bronchitis** is a clinical diagnosis defined by excessive secretion of bronchial mucus and is manifested by daily productive cough for 3 months or more in at least 2 consecutive years. **Emphysema** is a pathologic diagnosis that denotes abnormal permanent enlargement of air spaces distal to the terminal bronchiole, with destruction of their walls and without obvious fibrosis (see micrograph).

Fig.
Normal lung ***(A)*** compared with emphysema ***(B)*** at equivalent magnification, showing destruction of lung parenchyma and marked dilation of terminal air spaces in emphysema microscopically. (Reproduced, with permission, from Chandrasoma P, Taylor CR: Concise Pathology, 2nd ed. Originally published by Appleton & Lange. Copyright © 1995 by The McGraw-Hill Companies, Inc.)

Cigarette smoking is clearly the most important cause of COPD in North America and Western Europe. Nearly all smokers suffer an accelerated decline in lung function that is dose- and duration-dependent. Fifteen percent develop progressively disabling symptoms in their 40s and 50s. It is estimated that 80% of patients seen for COPD have significant exposure to tobacco smoke. The remaining 20% frequently have a combination of exposures to environmental tobacco smoke, occupational dusts and chemicals, and indoor air pollution from biomass fuel used for cooking and heating in poorly ventilated buildings. Outdoor air pollution, airway infection, familial factors, and allergy have also been implicated in chronic bronchitis, and hereditary factors (deficiency of $_1$-antiprotease [$_1$-antitrypsin]) have been implicated in COPD. The pathogenesis of emphysema may involve excessive lysis of elastin and other structural proteins in the lung matrix by elastase and other proteases derived from lung neutrophils, macrophages, and mononuclear cells. Atopy and the tendency for bronchoconstriction to develop in response to nonspecific airway stimuli may be important risks for COPD.

Clinical Findings

Symptoms and Signs

Patients with COPD characteristically present in the fifth or sixth decade of life complaining of excessive cough, sputum production, and shortness of breath. Symptoms have often been present for 10 years or more. Dyspnea is noted initially only on heavy exertion, but as the condition progresses it occurs with mild activity. In severe disease, dyspnea occurs at rest. As the disease progresses, two symptom patterns tend to emerge, historically referred to as "pink puffers" and "blue bloaters" (Table 9–7). These patterns were once thought to represent pure forms of emphysema and bronchitis, respectively, but this is a simplification of the anatomy and pathophysiology. Most COPD patients have pathologic evidence of both disorders, and their clinical course may reflect other factors such as central control of ventilation and concomitant sleep-disordered breathing.

Table 9–7. Patterns of disease in advanced COPD.

	Type A: Pink Puffer (Emphysema Predominant)	**Type B: Blue Bloater (Bronchitis Predominant)**
History and physical examination	Major complaint is dyspnea, often severe, usually presenting after age 50. Cough is rare, with scant clear, mucoid sputum. Patients are thin, with recent weight loss common. They appear uncomfortable, with evident use of accessory muscles of respiration. Chest is very quiet without	Major complaint is chronic cough, productive of mucopurulent sputum, with frequent exacerbations due to chest infections. Often presents in late 30s and 40s. Dyspnea usually mild, though patients may note limitations to exercise. Patients frequently overweight and cyanotic but seem

	adventitious sounds. No peripheral edema.	comfortable at rest. Peripheral edema is common. Chest is noisy, with rhonchi invariably present; wheezes are common.
Laboratory studies	Hemoglobin usually normal (12–15 g/dL). PaO_2 normal to slightly reduced (65–75 mm Hg) but SaO_2 normal at rest. $PaCO_2$ normal to slightly reduced (35–40 mm Hg). Chest radiograph shows hyperinflation with flattened diaphragms. Vascular markings are diminished, particularly at the apices.	Hemoglobin usually elevated (15–18 g/dL). PaO_2 reduced (45–60 mm Hg) and $PaCO_2$ slightly to markedly elevated (50–60 mm Hg). Chest radiograph shows increased interstitial markings ("dirty lungs"), especially at bases. Diaphragms are not flattened.

Pulmonary function tests	Airflow obstruction ubiquitous. Total lung capacity increased, sometimes markedly so. DL_{CO} reduced. Static lung compliance increased.	Airflow obstruction ubiquitous. Total lung capacity generally normal but may be slightly increased. DL_{CO} normal. Static lung compliance normal.
Special evaluations		
/ matching	Increased ventilation to high / areas, ie, high dead space ventilation.	Increased perfusion to low / areas.
Hemodynamics	Cardiac output normal to slightly low. Pulmonary artery pressures mildly elevated and increase with exercise.	Cardiac output normal. Pulmonary artery pressures elevated, sometimes markedly so, and worsen with exercise.

Nocturnal ventilation	Mild to moderate degree of oxygen desaturation not usually associated with obstructive sleep apnea.	Severe oxygen desaturation, frequently associated with obstructive sleep apnea.
Exercise ventilation	Increased minute ventilation for level of oxygen consumption. PaO_2 tends to fall, $PaCO_2$ rises slightly.	Decreased minute ventilation for level of oxygen consumption. PaO_2 may rise; $PaCO_2$ may rise significantly.

DL_{CO}, single-breath diffusing capacity for carbon monoxide; / , ventilation-perfusion.

Pneumonia, pulmonary hypertension, cor pulmonale, and chronic respiratory failure characterize the late stage of COPD. A hallmark of COPD is the exacerbation of symptoms beyond normal day-to-day variation, often including increased dyspnea, an increased frequency or severity of cough, increased sputum volume or change in sputum character. These exacerbations are commonly precipitated by infection (more often viral than bacterial) or environmental factors. Exacerbations of COPD vary widely in severity but typically require a change in regular therapy.

Laboratory Findings

Spirometry provides objective information about pulmonary function and assesses the results of therapy. Pulmonary function tests early in the course of COPD reveal only evidence of abnormal closing volume and reduced midexpiratory flow rate. Reductions in FEV_1 and in the ratio of forced expiratory volume to vital capacity (FEV_1% or FEV_1/FVC ratio) occur later. In severe disease, the FVC is markedly reduced. Lung volume measurements reveal a marked increase in residual volume (RV), an increase in total lung capacity (TLC), and an elevation of the RV/TLC ratio, indicative of air trapping, particularly in emphysema (see illustration).

Arterial blood gas measurements characteristically show no abnormalities early in COPD other than an increased A–a–DO_2. Indeed, they are unnecessary unless (1) hypoxemia or hypercapnia is suspected, (2) the FEV_1 is < 40% of predicted, or (3) there are clinical signs of right heart failure. Hypoxemia occurs in advanced disease, particularly when chronic bronchitis predominates. Compensated respiratory acidosis occurs in patients with chronic respiratory failure, particularly in chronic bronchitis, with worsening of acidemia during acute exacerbations.

Examination of the sputum may reveal *Streptococcus pneumoniae*, *H influenzae*, or *Moraxella catarrhalis*. Positive sputum cultures are poorly correlated with acute exacerbations, and research techniques demonstrate evidence of preceding viral infection in a majority of patients with exacerbations. The ECG may show sinus tachycardia and, in advanced disease, chronic pulmonary hypertension may produce electrocardiographic abnormalities typical of cor pulmonale (see ECG). Supraventricular arrhythmias (multifocal atrial tachycardia, atrial flutter, and atrial fibrillation) and ventricular irritability also occur.

Fig.

Right atrial and right ventricular hypertrophy. The P waves are abnormally tall in leads II, III, and aVF, indicating right atrial abnormality. The frontal plane QRS axis is oriented rightward (deep S in I) and superiorly (QS complexes in II, III, and aVF); the axis is -110 degrees. A tall R wave is present in V_1. The rightward axis and tall R wave in V_1 indicate right ventricular hypertrophy. In the presence of right ventricular hypertrophy, QS complexes need not indicate myocardial infarction. Clinical Electrocardiography, 13th ed. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Imaging

Radiographs of patients with chronic bronchitis typically show only nonspecific peribronchial and perivascular markings. Plain radiographs are insensitive for the diagnosis of emphysema; they show hyperinflation with flattening of the diaphragm or peripheral arterial deficiency in about half of cases (see x-ray); (see x-ray). CT of the chest, particularly using a high-resolution reconstruction algorithm, is more sensitive and specific than plain radiographs for the diagnosis of emphysema. Pulmonary hypertension may be suggested by enlargement of central pulmonary arteries in advanced disease. Doppler echocardiography is an effective noninvasive way to estimate pulmonary artery pressure if pulmonary hypertension is suspected.

Bullous disease. There is almost a complete paucity of lung markings in both lungs. The edge of some bullae can be seen in the left lung. (Courtesy of H Goldberg.)

Differential Diagnosis

Clinical, imaging, and laboratory findings should enable the clinician to distinguish COPD from other obstructive pulmonary disorders such as bronchial asthma, bronchiectasis, cystic fibrosis, bronchopulmonary mycosis, and central airflow obstruction. Simple asthma is characterized by complete or near-complete reversibility of airflow obstruction. Bronchiectasis is distinguished from COPD by features such as recurrent pneumonia and hemoptysis, digital clubbing, and characteristic imaging abnormalities. Patients with severe $_1$-antiprotease ($_1$-antitrypsin) deficiency are recognized by family history and the appearance of panacinar bibasilar emphysema early in life, usually in the third or fourth decade; hepatic cirrhosis and hepatocellular carcinoma may occur. Cystic fibrosis occurs in children and younger adults. Rarely, mechanical obstruction of the central airways simulates COPD. Flow-volume loops may help separate patients with central airway obstruction from those with diffuse intrathoracic airway obstruction characteristic of COPD.

Complications

Acute bronchitis, pneumonia, pulmonary thromboembolism, and concomitant left ventricular failure may worsen otherwise stable COPD. Pulmonary hypertension, cor pulmonale, and chronic respiratory failure are common in advanced COPD. Spontaneous pneumothorax occurs in a small fraction of patients with emphysema. Hemoptysis may result from chronic bronchitis or may signal bronchogenic carcinoma.

Prevention

COPD is largely preventable through elimination of long-term exposure to tobacco smoke. Smokers with early evidence of airflow limitation can significantly alter their disease by smoking cessation. Smoking cessation slows the decline in FEV_1 in middle-aged smokers with mild airways obstruction. Vaccination against influenza and pneumococcal infection may also be of benefit.

Treatment

The treatment of COPD is guided by the severity of symptoms or the presence of an exacerbation or stable symptoms. Standards for the management of patients with stable COPD and COPD exacerbations have been published by the American Thoracic Society and the Global Initiative for Obstructive Lung Disease (GOLD), a joint expert committee of the NHLBI and the WHO. See Chapter 37: Disorders Due to Physical Agents for a discussion of air travel in patients with lung disease.

Ambulatory Patients

Smoking cessation

The single most important intervention in smokers with COPD is to encourage smoking cessation. Simply telling a patient to quit succeeds 5% of the time. Behavioral approaches, ranging from clinician advice to intensive group programs, may improve cessation rates. Pharmacologic therapy includes nicotine replacement, (transdermal patch, gum, lozenge, inhaler, or nasal spray), bupropion, and varenicline (a partial agonist of nicotine acetylcholine receptors) (see Chapter 1: Disease Prevention & Health Promotion). Combined pharmacotherapies (two forms of nicotine replacement, or nicotine replacement and bupropion), with or without behavioral approaches have also been recommended. The

Lung Health Study reported 22% sustained abstinence at 5 years in their intervention group (behavior modification plus nicotine gum). Varenicline has proved effective but wider use has revealed significant CNS side effects, including some reports of an increase in suicide.

Oxygen therapy

The only drug therapy that is documented to improve the natural history of COPD is supplemental oxygen in those patients with resting hypoxemia. Proved benefits of home oxygen therapy in hypoxemic patients include longer survival, reduced hospitalization needs, and better quality of life. Survival in hypoxemic patients with COPD treated with supplemental oxygen therapy is directly proportionate to the number of hours per day oxygen is administered: in patients treated with continuous oxygen, the survival after 36 months is about 65%—significantly better than the survival rate of about 45% in those who are treated with only nocturnal oxygen. Oxygen by nasal prongs must be given at least 15 hours a day unless therapy is intended only for exercise or sleep.

Requirements for Medicare coverage for a patient's home use of oxygen and oxygen equipment are listed in Table 9–8. Arterial blood gas analysis is preferred over pulse oximetry to guide initial oxygen therapy. Hypoxemic patients with pulmonary hypertension, chronic cor pulmonale, erythrocytosis, impaired cognitive function, exercise intolerance, nocturnal restlessness, or morning headache are particularly likely to benefit from home oxygen therapy.

Table 9–8. Home oxygen therapy: requirements for Medicare coverage.[1]
Group I (any of the following):
1. PaO_2 55 mm Hg or SaO_2 88% taken at rest breathing room air, while awake.
2. During sleep (prescription for nocturnal oxygen use only):
a. PaO_2 55 mm Hg or SaO_2 88% for a patient whose awake, resting, room air PaO_2 is 56 mm Hg or SaO_2 89%,
or
b. Decrease in $PaO_2 > 10$ mm Hg or decrease in $SaO_2 > 5\%$ associated with symptoms or signs reasonably attributed to hypoxemia (eg, impaired cognitive processes, nocturnal restlessness, insomnia).
3. During exercise (prescription for oxygen use only during exercise):

a. PaO_2 55 mg Hg or SaO_2 88% taken during exercise for a patient whose awake, resting, room air PaO_2 is 56 mm Hg or SaO_2 89%,
and
b. There is evidence that the use of supplemental oxygen during exercise improves the hypoxemia that was demonstrated during exercise while breathing room air.
Group II[2:]
PaO_2 = 56–59 mm Hg or SaO_2 = 89% if there is evidence of any of the following:
1. Dependent edema suggesting congestive heart failure.
2. P pulmonale on ECG (P wave > 3 mm in standard leads II, III, or aVF).
3. Hematocrit > 56%.

[1] Health Care Financing Administration, 1989.

[2] Patients in this group must have a second oxygen test 3 months after the initial oxygen set-up.

Home oxygen may be supplied by liquid oxygen systems (LOX), compressed gas cylinders, or oxygen concentrators. Most patients benefit from having both stationary and portable systems. For most patients, a flow rate of 1–3 L/min achieves a PaO_2 greater than 55 mm Hg. The monthly cost of home oxygen therapy ranges from $300.00 to $500.00 or more, higher for liquid oxygen systems. Medicare covers approximately 80% of home oxygen expenses. **Transtracheal oxygen** is an alternative method of delivery and may be useful for patients who require higher flows of oxygen than can be delivered via the nose or who are experiencing troublesome side effects from nasal delivery such as nasal drying or epistaxis. Reservoir nasal cannulas or "pendants" and demand (pulse) oxygen delivery systems are also available to conserve oxygen.

Inhaled bronchodilators

Bronchodilators are agents in the pharmacologic management of patients with COPD. Bronchodilators do not alter the inexorable decline in lung function that is a hallmark of the disease, but they offer some patients improvement in symptoms, exercise tolerance, and overall health status. Aggressiveness of bronchodilator therapy should be matched to the severity of the patient's disease. In patients who experience no symptomatic improvement, bronchodilators should be discontinued.

The most commonly prescribed short-acting bronchodilators are the anticholinergic ipratropium bromide and $_2$-agonists (eg, albuterol, metaproterenol), delivered by MDI or as an inhalation solution by nebulizer. Ipratropium bromide is generally preferred to the short-acting $_2$-agonists as a first-line agent because of its longer duration of action and absence of sympathomimetic side effects. Some studies have suggested that ipratropium achieves superior bronchodilation in COPD patients. Typical doses are two to four puffs (36–72 mcg) every 6 hours. Short-acting $_2$-agonists are less expensive and have a more rapid onset of action, commonly leading to greater patient satisfaction. At maximal doses, $_2$-agonists have bronchodilator action equivalent to that of ipratropium but may cause tachycardia, tremor, or hypokalemia. There does not appear to be any advantage of scheduled use of short-acting $_2$-agonists compared with as-needed administration. Use of both short-acting $_2$-agonists and anticholinergics at submaximal doses leads to improved bronchodilation compared with either agent alone but does not improve dyspnea.

Long-acting $_2$-agonists (eg, formoterol, salmeterol) and anticholinergics (tiotropium) appear to achieve bronchodilation that is equivalent or superior to what is experienced with ipratropium, in addition to similar improvements on health status. Although they are more expensive than short-acting agents, long-acting bronchodilators may have superior clinical efficacy in persons with advanced disease. A recent large randomized controlled trial (RCT) of long-term administration of tiotropium added to standard therapy reported fewer exacerbations or hospitalizations, and improved dyspnea scores, in the tiotropium group. Tiotropium had no effect on long-term decline in lung function, however. Another RCT comparing the effects of tiotropium with those of salmeterol-fluticasone in COPD over 2 years reported no difference in the risk of exacerbation. However, the incidence of pneumonia was higher in the salmeterol-fluticasone group, yet the dyspnea scores were lower, and there was a mortality benefit compared with tiotropium. This last finding awaits confirmation in further studies.

Whether there is a mortality benefit associated with salmeterol-fluticasone therapy remains controversial since serious concerns have been raised about the safety of both long-acting $_2$-agonists and anticholinergics. Two large RCTs in asthmatic patients reported an increase in exacerbations and mortality in patients treated with salmeterol. These findings have not been observed in COPD patients, however, and several studies report a trend toward lower mortality in patients treated with salmeterol alone, compared with placebo. Several small studies and a recent meta-analysis have reported an increase in cardiovascular events among patients treated with long- and short-acting anticholinergics. In contrast, the 4-year tiotropium trial reported fewer cardiovascular events in the intervention group. Most practitioners believe that the documented benefits of anticholinergic therapy outweigh the potential risks, but this is an area of uncertainty and ongoing study.

Corticosteroids

Multiple large clinical trials have reported a reduction in the frequency of COPD exacerbations and an increase in self-reported functional status in COPD patients treated with inhaled corticosteroids. These same trials demonstrate no effect of inhaled corticosteroids on mortality or the characteristic decline in lung function experienced by COPD patients. At this time, inhaled corticosteroids alone should not be considered first-line therapy in stable COPD patients, who benefit more from bronchodilators, smoking cessation, and pulmonary rehabilitation.

Combination therapy with an inhaled corticosteroid and a long-acting $_2$-agonist reduces the frequency of COPD exacerbations and improves self-reported functional status in COPD patients, compared with placebo or sole use of inhaled corticosteroids, long-acting $_2$-agonists, or anticholinergics. Addition of an inhaled corticosteroid/long-acting $_2$-agonist to tiotropium therapy in COPD patients does not reduce the frequency of COPD exacerbations but did improve hospitalization rates as well as self-reported functional status in one RCT.

Apart from acute exacerbations, COPD is not generally responsive to oral corticosteroid therapy. Only 10–20% of stable outpatients with COPD given oral corticosteroids will have a greater than 20% increase in FEV_1 compared with patients receiving placebo. There may be a subset of steroid-responsive COPD patients more likely to benefit from long-term oral or inhaled corticosteroids. Since there are no clinical predictors to identify such responders, empiric trials of oral corticosteroids are common. Current research provides little guidance to interpret clinically relevant benefit and clinically significant changes in spirometry, however. If empiric trials of oral corticosteroids are conducted, rigorous outcome assessment as advocated by the McMaster group is appropriate. The use of oral or systemic corticosteroids has well-recognized adverse effects, and it seems prudent management to seek to minimize cumulative oral corticosteroid exposure. Some patients may be truly "corticosteroid-dependent," but clinical experience suggests that this is rare when all other available therapies are optimized.

Theophylline

Oral **theophylline** is a fourth-line agent for treating patients with COPD who do not achieve adequate symptom control with anticholinergics, $_2$-agonists, and inhaled corticosteroid therapy. Sustained-release theophylline improves hemoglobin saturation during sleep in COPD patients and is a first-line agent for those with sleep-related breathing disorders. Theophylline has fallen out of favor because of its narrow therapeutic window and the availability of potent inhaled bronchodilators. Nonetheless, theophylline does improve dyspnea, exercise performance, and pulmonary function in many patients with stable COPD. Its benefits may result from anti-inflammatory properties and extrapulmonary effects on diaphragm strength, myocardial contractility, and kidney function.

Antibiotics

Antibiotics are commonly prescribed to outpatients with COPD for the following indications: (1) to treat an acute exacerbation, (2) to treat acute bronchitis, and (3) to prevent acute exacerbations of chronic bronchitis (prophylactic antibiotics). Antibiotics appear to improve outcomes slightly in the first two situations, but there is no convincing evidence to support the use of prophylactic antibiotics in patients with COPD. Patients with a COPD exacerbation associated with dyspnea and a change in the quantity or character of sputum benefit the most from antibiotic therapy. In the past, common agents included trimethoprim-sulfamethoxazole (160/800 mg every 12 hours), amoxicillin (500 mg every 8 hours), or doxycycline (100 mg every 12 hours) given for 7–10 days. Prescribing patterns have changed, and a recent meta-analysis of antibiotic therapy in acute bronchitis complicating COPD found macrolides (azithromycin 500 mg followed by 250 mg daily for 5 days), fluoroquinolones (ciprofloxacin 500 mg every 12 hours), and amoxicillin-clavulanate (875/125 mg every 12 hours) to be more effective than older therapies. There are few controlled trials of antibiotics in severe COPD exacerbations but prompt administration of antibiotics is appropriate, particularly in those with risk factors for poor outcomes.

Pulmonary rehabilitation

Graded aerobic physical exercise programs (eg, walking 20 minutes three times weekly or bicycling) are helpful to prevent deterioration of physical condition and to improve patients' ability to carry out daily activities. Training of inspiratory muscles by inspiring against progressively larger resistive loads reduces dyspnea, improves exercise tolerance, health status, and respiratory muscle strength in some but not all patients. Pursed-lip breathing to slow the rate of breathing and abdominal breathing exercises to relieve fatigue of accessory muscles of respiration may reduce dyspnea in some patients. Many patients undergo these exercise and educational interventions in a structured rehabilitation program. In a number of studies, pulmonary rehabilitation has been shown to improve exercise capacity, decrease hospitalizations, and enhance quality of life. Referral to a comprehensive rehabilitation program is recommended in patients who have severe dyspnea, reduced quality of life, or frequent hospitalizations despite optimal medical therapy.

Other measures

In patients with chronic bronchitis, increased mobilization of secretions may be accomplished through the use of adequate systemic hydration, effective cough training methods, or use of a hand-held flutter device and postural drainage, sometimes with chest percussion or vibration. Postural drainage and chest percussion should be used only in selected patients with excessive amounts of retained secretions that cannot be cleared by coughing and other methods; these measures are of no benefit in pure emphysema. Expectorant-mucolytic therapy has generally been regarded as unhelpful in patients with chronic bronchitis. Cough suppressants and sedatives should be avoided as routine measures.

Human $_1$-antitrypsin is available for replacement therapy in emphysema due to congenital deficiency (PiZZ or null genotype) of $_1$-antiprotease ($_1$-antitrypsin). Patients over 18 years of age with airflow obstruction by spirometry and serum levels less than 11 mcmol/L (~50 mg/dL) are potential candidates for replacement therapy. There is no evidence that replacement therapy is beneficial to heterozygotes (eg, PiMZ) with low-normal serum levels, although such patients may be at slightly increased risk for emphysema, especially in the setting of tobacco smoke exposure. $_1$-Antitrypsin is administered intravenously in a dose of 60 mg/kg body weight once weekly.

Severe dyspnea in spite of optimal medical management may warrant a clinical trial of an opioid. Sedative-hypnotic drugs (eg, diazepam, 5 mg three times daily) are controversial in intractable dyspnea but may benefit very anxious patients. Intermittent negative-pressure (cuirass) ventilation and transnasal positive-pressure ventilation at home to rest the respiratory muscles are promising approaches to improve respiratory muscle function and reduce dyspnea in patients with severe COPD. A bilevel transnasal ventilation system has been reported to reduce dyspnea in ambulatory patients with severe COPD, but the long-term benefits of this approach and compliance with it have not been defined.

Hospitalized Patients

Management of the hospitalized patient with an acute exacerbation of COPD includes supplemental oxygen, inhaled ipratropium bromide plus $_2$-agonists, and broad-spectrum antibiotics, corticosteroids and, in selected cases, chest physiotherapy. Theophylline should not be initiated in the acute setting, but patients taking theophylline prior to acute hospitalization should have their theophylline serum levels measured and maintained in the therapeutic range. Oxygen therapy should not be withheld for fear of worsening respiratory acidemia; hypoxemia is more detrimental than hypercapnia. Cor pulmonale usually responds to measures that reduce pulmonary artery pressure, such as supplemental oxygen and correction of acidemia; bed rest, salt restriction, and diuretics may add some benefit. Cardiac arrhythmias, particularly multifocal atrial tachycardia, usually respond to aggressive treatment of COPD itself. Atrial flutter may require DC cardioversion after initiation of the above therapy. If progressive respiratory failure ensues, tracheal intubation and mechanical ventilation are necessary. In clinical trials of COPD patients with hypercapnic acute respiratory failure, noninvasive positive-pressure ventilation (NPPV) delivered via face mask reduced the need for intubation and shortened lengths of stay in the intensive care unit (ICU). Other studies have suggested a lower risk of health care-associated infections and less use of antibiotics in COPD patients treated with NPPV. These benefits do not appear to extend to hypoxemic respiratory failure or to patients with acute lung injury or ARDS.

Surgery for COPD

Lung transplantation

Experience with both single and bilateral sequential lung transplantation for severe COPD is extensive. Requirements for lung transplantation are severe lung disease, limited activities of daily living, exhaustion of medical therapy, ambulatory status, potential for pulmonary rehabilitation, limited life expectancy without transplantation, adequate function of other organ systems, and a good social support system. Average total charges for lung transplantation through the end of the first postoperative year exceed $250,000. The 2-year survival rate after lung transplantation for COPD is 75%. Complications include acute rejection, opportunistic infection, and obliterative bronchiolitis. Substantial improvements in pulmonary function and exercise performance have been noted after transplantation.

Lung volume reduction surgery

Lung volume reduction surgery (LVRS), or reduction pneumoplasty, is a surgical approach to relieve dyspnea and improve exercise tolerance in patients with advanced diffuse emphysema and lung hyperinflation. Bilateral resection of 20–30% of lung volume in selected patients results in modest improvements in pulmonary function, exercise performance, and dyspnea. The duration of any improvement as well as any mortality benefit remains uncertain. Prolonged air leaks occur in up to 50% of patients postoperatively. Mortality rates in centers with the largest experience with LVRS range from 4% to 10%.

The National Emphysema Treatment Trial compared LVRS with medical treatment in a randomized, multicenter clinical trial of 1218 patients with severe emphysema. Overall, surgery improved exercise capacity but not mortality when compared with medical therapy. The persistence of this benefit remains to be defined. Subgroup analysis suggested that patients with upper lobe predominant emphysema and low exercise capacity might have improved survival, while other groups suffered excess mortality when randomized to surgery.

Bullectomy

Bullectomy is an older surgical procedure for palliation of dyspnea in patients with severe bullous emphysema. Bullectomy is most commonly pursued when a single bulla occupies at least 30–50% of the hemithorax. In this procedure, the surgeon removes a large emphysematous bulla that demonstrates no ventilation or perfusion on lung scanning and compresses adjacent lung with preserved function. Bullectomy can be performed with a CO_2 laser via thoracoscopy.

Prognosis

The outlook for patients with clinically significant COPD is poor. The degree of pulmonary dysfunction at the time the patient is first seen is an important predictor of survival: median survival of patients with severe FEV$_1$ 1 L is about 4 years. A multidimensional index (the BODE index), which includes body mass index (BMI), airway obstruction (FEV$_1$), dyspnea (Medical Research Council dyspnea score), and exercise capacity is a tool that predicts death and hospitalization better than FEV$_1$ alone. Comprehensive care programs, cessation of smoking, and supplemental oxygen may reduce the rate of decline of pulmonary function, but therapy with bronchodilators and other approaches probably has little, if any, impact on the natural course of COPD.

Dyspnea at the end of life can be extremely uncomfortable and distressing to the patient and family. Dyspnea can be effectively managed with a combination of medications and mechanical interventions. As patients near the end of life, meticulous attention to palliative care is essential (see Chapter 5: Palliative Care & Pain Management).

When to Refer

- COPD onset occurs before the age of 40.
- Frequent exacerbations (two or more a year) despite optimal treatment.
- Severe or rapidly progressive COPD.
- Symptoms disproportionate to the severity of airflow obstruction.

- Need for long-term oxygen therapy.
- Onset of comorbid illnesses (such as bronchiectasis, heart failure, or lung cancer).

When to Admit

- Severe symptoms or acute worsening that fails to respond to outpatient management.
- Acute or worsening hypoxemia, hypercapnia, peripheral edema, or change in mental status.
- Inadequate home care, or inability to sleep or maintain nutrition/hydration due to symptoms.
- The presence of high-risk comorbid conditions.

Bronchiectasis

Essentials of Diagnosis

- Chronic productive cough with dyspnea and wheezing.
- Recurrent pulmonary infections requiring antibiotics.
- A preceding history of recurrent pulmonary infections or inflammation, or a predisposing condition.
- Radiographic findings of dilated, thickened airways and scattered, irregular opacities.

General Considerations

Bronchiectasis is a congenital or acquired disorder of the large bronchi characterized by permanent, abnormal dilation and destruction of bronchial walls. It may be caused by recurrent inflammation or infection of the airways and may be localized or diffuse. Cystic fibrosis causes about half of all cases of bronchiectasis. Other causes include lung infection (tuberculosis, fungal infections, lung abscess, pneumonia), abnormal lung defense mechanisms (humoral immunodeficiency, $_1$-antiprotease [$_1$-antitrypsin] deficiency with cigarette smoking, mucociliary clearance disorders, rheumatic diseases), and localized airway obstruction (foreign body, tumor, mucoid impaction). Immunodeficiency states that may lead to bronchiectasis include congenital or acquired panhypogammaglobulinemia; common variable immunodeficiency; selective IgA, IgM, and IgG subclass deficiencies; and acquired immunodeficiency from cytotoxic therapy, AIDS, lymphoma, multiple myeloma, leukemia, and chronic kidney and liver diseases. However, most patients with bronchiectasis have panhypergammaglobulinemia, presumably reflecting an immune system response to chronic airway infection. Acquired primary bronchiectasis is now uncommon in the United States because of improved control of bronchopulmonary infections.

Clinical Findings

Symptoms and Signs

Symptoms of bronchiectasis include chronic cough with production of copious amounts of purulent sputum, hemoptysis, and pleuritic chest pain. Dyspnea and wheezing occur in 75% of patients. Weight loss, anemia, and other systemic manifestations are common. Physical findings are nonspecific, but persistent crackles at the lung bases are common. Clubbing is infrequent in mild cases but is common in severe disease (see Plate 47). Copious, foul-smelling, purulent sputum is characteristic. Obstructive pulmonary dysfunction with hypoxemia is seen in moderate or severe disease.

Imaging

Radiographic abnormalities include dilated and thickened bronchi that may appear as "tram-tracks" or as ring-like markings. Scattered irregular opacities, atelectasis, and focal consolidation may be present. High-resolution CT is the diagnostic study of choice.

Treatment

Treatment of acute exacerbations consists of antibiotics (selected on the basis of sputum smears and cultures), daily chest physiotherapy with postural drainage and chest percussion, and inhaled bronchodilators. Hand-held flutter valve devices may be as effective as chest physiotherapy in clearing secretions. Empiric oral antibiotic therapy for 10–14 days with amoxicillin or amoxicillin-clavulanate (500 mg every 8 hours), ampicillin or tetracycline (250–500 mg four times daily), or trimethoprim-sulfamethoxazole (160/800 mg every 12 hours) is reasonable therapy in an acute exacerbation if a specific bacterial pathogen cannot be isolated. It is important to screen patients for infection with nontuberculous mycobacteria because these organisms may underlie a lack of treatment response. Preventive or suppressive treatment is sometimes given to stable outpatients with bronchiectasis who have copious purulent sputum. Clinical trial data to guide this practice are scant. Common regimens include macrolides (azithromycin, 500 mg three times a week; erythromycin, 500 mg twice daily), high-dose (3 g/d) amoxicillin or alternating cycles of the antibiotics listed above given orally for 2–4 weeks. In patients with underlying cystic fibrosis, inhaled aerosolized aminoglycosides reduce colonization by *Pseudomonas* species, improve FEV_1 and reduce hospitalizations; in non–cystic fibrosis bronchiectasis, adding inhaled tobramycin to oral ciprofloxacin for acute exacerbations due to *Pseudomonas* decreases microbial sputum burden but without apparent clinical benefit. Complications of bronchiectasis include hemoptysis, cor pulmonale, amyloidosis, and secondary visceral abscesses at distant sites (eg, brain). Bronchoscopy is sometimes necessary to evaluate hemoptysis, remove retained secretions, and rule out obstructing airway lesions. Massive hemoptysis may require embolization of bronchial arteries or surgical resection. Surgical resection is otherwise reserved for the few patients with localized bronchiectasis and adequate pulmonary function in whom conservative management fails.

Allergic Bronchopulmonary Mycosis

Allergic bronchopulmonary mycosis is a pulmonary hypersensitivity disorder caused by allergy to fungal antigens that colonize the tracheobronchial tree. It usually occurs in atopic asthmatic individuals who are 20–40 years of age, in response to antigens of *Aspergillus* species. For this reason, the disorder is commonly referred to as allergic bronchopulmonary aspergillosis (ABPA). Primary criteria for the diagnosis of ABPA include (1) a clinical history of asthma, (2) peripheral eosinophilia, (3) immediate skin reactivity to *Aspergillus* antigen, (4) precipitating antibodies to *Aspergillus* antigen, (5) elevated serum IgE levels, (6) pulmonary infiltrates (transient or fixed), and (7) central bronchiectasis. If the first six of these seven primary criteria are present, the diagnosis is almost certain. Secondary diagnostic criteria include identification of *Aspergillus* in sputum, a history of brown-flecked sputum, and late skin reactivity to *Aspergillus* antigen. High-dose prednisone (0.5–1 mg/kg orally per day) for at least 2 months is the treatment of choice, and the response in early disease is usually excellent. Depending on the overall clinical situation, prednisone can then be cautiously tapered. Relapses are frequent, and protracted or repeated treatment with corticosteroids is not uncommon. Patients with corticosteroid-dependent disease may benefit from itraconazole (200 mg orally once or twice daily) without added toxicity. Bronchodilators (Table 9–6) are also helpful. Complications include hemoptysis, severe bronchiectasis, and pulmonary fibrosis.

Cystic Fibrosis

Essentials of Diagnosis

- Chronic or recurrent cough, sputum production, dyspnea, and wheezing.
- Recurrent infections or chronic colonization of the airways with nontypeable *H influenzae*, mucoid and nonmucoid *Pseudomonas aeruginosa*, *Staphylococcus aureus*, or *Burkholderia cepacia*.
- Pancreatic insufficiency, recurrent pancreatitis, distal intestinal obstruction syndrome, chronic hepatic disease, nutritional deficiencies, or male urogenital abnormalities.

- Bronchiectasis and scarring on chest radiographs.
- Airflow obstruction on spirometry.
- Sweat chloride concentration above 60 mEq/L on two occasions or gene mutation known to cause cystic fibrosis.

General Considerations

Cystic fibrosis is the most common cause of severe chronic lung disease in young adults and the most common fatal hereditary disorder of whites in the United States. It is an autosomal recessive disorder affecting about one in 3200 whites; 1 in 25 is a carrier. Cystic fibrosis is caused by abnormalities in a membrane chloride channel (the cystic fibrosis transmembrane conductance regulator [CFTR] protein) that results in altered chloride transport and water flux across the apical surface of epithelial cells. Almost all exocrine glands produce an abnormal mucus that obstructs glands and ducts. Obstruction results in glandular dilation and damage to tissue. In the respiratory tract, inadequate hydration of the tracheobronchial epithelium impairs mucociliary function. High concentrations of DNA in airway secretions (due to chronic airways inflammation and autolysis of neutrophils) increases sputum viscosity. Over 1000 mutations in the gene that encodes CFTR have been described, and at least 230 mutations are known to be associated with clinical abnormalities. The mutation referred to as F508 accounts for about 60% of cases of cystic fibrosis.

Over one-third of the nearly 30,000 cystic fibrosis patients in the United States are adults. Because of the wide range of alterations seen in the CFTR protein structure and function, cystic fibrosis in adults may present with a variety of pulmonary and nonpulmonary manifestations. Pulmonary manifestations in adults include acute and chronic bronchitis, bronchiectasis, pneumonia, atelectasis, and peribronchial and parenchymal scarring. Pneumothorax and hemoptysis are common. Hypoxemia, hypercapnia, and cor pulmonale occur in advanced cases. Biliary cirrhosis and gallstones may occur. Nearly all men with cystic fibrosis have congenital bilateral absence of the vas deferens with azoospermia. Patients with cystic fibrosis have an increased risk of malignancies of the gastrointestinal tract, osteopenia, and arthropathies.

Clinical Findings

Symptoms and Signs

Cystic fibrosis should be suspected in a young adult with a history of chronic lung disease (especially bronchiectasis), pancreatitis, or infertility. Cough, sputum production, decreased exercise tolerance, and recurrent hemoptysis are typical complaints. Patients also often complain of facial (sinus) pain or pressure and purulent nasal discharge. Steatorrhea, diarrhea, and abdominal pain are also common. Digital clubbing (see photograph), increased anteroposterior chest diameter, hyperresonance to percussion, and apical crackles are noted on physical examination. Sinus tenderness, purulent nasal secretions, and nasal polyps may also be seen.

Laboratory Findings

Arterial blood gas studies often reveal hypoxemia and, in advanced disease, a chronic, compensated respiratory acidosis. Pulmonary function studies show a mixed obstructive and restrictive pattern. There is a reduction in FVC, airflow rates, and TLC. Air trapping (high ratio of RV to TLC) and reduction in pulmonary diffusing capacity are common.

Imaging

Hyperinflation is seen early in the disease process. Peribronchial cuffing, mucus plugging, bronchiectasis (ring shadows and cysts), increased interstitial markings, small rounded peripheral opacities, and focal atelectasis may be seen separately or in various combinations (see x-ray). Pneumothorax can also be seen. Thin-section CT scanning may confirm the presence of bronchiectasis.

Fig.

Cystic fibrosis. This chest radiograph is of an adult with advanced cystic fibrosis, resulting in huge blebs in both apices, considerable pulmonary fibrosis, and restrictive lung disease. (Courtesy of H Goldberg.)

Diagnosis

The quantitative pilocarpine iontophoresis sweat test reveals elevated sodium and chloride levels (> 60 mEq/L) in the sweat of patients with cystic fibrosis. Two tests on different days are required for accurate diagnosis. Facilities must perform enough tests to maintain laboratory proficiency and quality. A normal sweat chloride test does not exclude the diagnosis. Genotyping or other alternative diagnostic studies (such as measurement of nasal membrane potential difference, semen analysis, or assessment of pancreatic function) should be pursued if the test is repeatedly negative but there is a high clinical suspicion of cystic fibrosis. Standard genotyping is a limited diagnostic tool because it screens for only a fraction of the known cystic fibrosis mutations, although complete genetic testing is available.

Treatment

Early recognition and comprehensive multidisciplinary therapy improve symptom control and the chances of survival. Referral to a regional cystic fibrosis center is strongly recommended. Conventional treatment programs focus on the following areas: clearance and reduction of lower airway secretions, reversal of bronchoconstriction, treatment of respiratory tract infections and airway bacterial burden, pancreatic enzyme replacement, and nutritional and psychosocial support (including genetic and occupational counseling). The Pulmonary Therapies Committee, established by the Cystic Fibrosis Foundation, has issued evidenced-based recommendations regarding long-term use of medications for maintenance of lung function and reduction of exacerbations in patients with cystic fibrosis.

Clearance of lower airway secretions can be promoted by postural drainage, chest percussion or vibration techniques, positive expiratory pressure (PEP) or flutter valve breathing devices, directed cough, and other breathing techniques; these approaches require detailed patient instruction by experienced personnel. Sputum viscosity in cystic fibrosis is increased by the large quantities of extracellular DNA that result from chronic airway inflammation and autolysis of neutrophils. Inhaled recombinant human deoxyribonuclease (rhDNase, dornase alpha) cleaves extracellular DNA in sputum; when administered long-term at a daily nebulized dose of

2.5 mg, this therapy leads to improved FEV_1 and reduces the risk of cystic fibrosis–related respiratory exacerbations and the need for intravenous antibiotics. Pharyngitis, laryngitis, and voice alterations are common adverse effects. Inhalation of hypertonic saline has been associated with small improvements in pulmonary function and fewer pulmonary exacerbations. The beneficial effects of hypertonic saline in cystic fibrosis may derive from improved airway mucous clearance. Short-term antibiotics are used to treat active airway infections based on results of culture and susceptibility testing of sputum. *S aureus* (including methicillin-resistant strains) and a mucoid variant of *P aeruginosa* are commonly present. *H influenzae, Stenotrophomonas maltophilia*, and *B cepacia* (a highly drug-resistant organism) are occasionally isolated. Long-term antibiotics (azithromycin, 500 mg orally three times a week, and inhalation of an aerosolized tobramycin solution) are helpful in slowing disease progression and reducing exacerbations in patients with cultures of airway secretions persistently positive for *P aeruginosa*.

Inhaled bronchodilators (eg, albuterol, two puffs every 4 hours as needed) should be considered in patients who demonstrate an increase of at least 12% in FEV_1 after an inhaled bronchodilator. Vaccination against pneumococcal infection and annual influenza vaccination are advised. Screening of family members and genetic counseling are suggested.

Lung transplantation is currently the only definitive treatment for advanced cystic fibrosis. Double-lung or heart-lung transplantation is required. A few transplant centers offer living lobar lung transplantation to selected patients. The 3-year survival rate following transplantation for cystic fibrosis is about 55%.

Prognosis

The longevity of patients with cystic fibrosis is increasing, and the median survival age is over 35 years. Death occurs from pulmonary complications (eg, pneumonia, pneumothorax, or hemoptysis) or as a result of terminal chronic respiratory failure and cor pulmonale.

Bronchiolitis

Bronchiolitis is a generic term applied to varied inflammatory processes that affect the bronchioles, which are small conducting and respiratory airways < 2 mm in diameter. In infants and children, bronchiolitis is common and usually caused by respiratory syncytial virus or adenovirus infection. In adults, bronchiolitis is encountered in a variety of clinical settings, including infections, connective tissue diseases, inhalational injuries, drug reactions, and allograft transplantation. No single classification scheme has been widely accepted and, as a result, there is a confusing and overlapping array of terms to describe these disorders from the viewpoints of the clinician, the radiologist, and the pathologist.

The pathologic classification has two variants. **Constrictive bronchiolitis** (also referred to as obliterative bronchiolitis, or bronchiolitis obliterans) is characterized by chronic inflammation, concentric scarring, and smooth muscle hypertrophy causing luminal obstruction. These patients have airflow obstruction on spirometry, minimal radiographic abnormalities, and a progressive, deteriorating clinical course. **Proliferative bronchiolitis** occurs when there is an organizing intraluminal exudate, consisting of fibroblasts, foamy macrophages, and other cells that obstruct the lumen. When this exudate extends to the alveolar space, the pattern is referred to as bronchiolitis obliterans with organizing pneumonia (BOOP; now more commonly referred to as **cryptogenic organizing pneumonitis** [COP]) (see Table 9–14).

The clinical classification approach divides patients into groups based primarily upon etiology. Inhalational injuries, postinfectious, and drug-induced causes are identified by association with a known exposure or illness prior to the onset of symptoms. Disorders associated with bronchiolitis include organ transplantation, connective tissue diseases, and hypersensitivity pneumonitis. Idiopathic cases are characterized by the insidious onset of dyspnea or cough, and include **COP.** This disorder affects men and women between the ages of 50 and 70 years, typically with a dry cough, dyspnea, and constitutional symptoms present for weeks to months prior to presentation. Pulmonary function testing typically shows a restrictive ventilatory defect. The chest radiograph frequently shows bilateral patchy, ground-glass or alveolar infiltrates, although other patterns have been described (see Table 9–14). Corticosteroids are effective in two-thirds of patients, and improvement can be prompt. Corticosteroids are effective in two-thirds of patients, and improvement can be prompt. Therapy is initiated with prednisone at 1 mg/kg/d for 1–3 months. The dose is then tapered slowly to 20–40 mg/d, depending on the response, and weaned over the subsequent 3–6 months as tolerated. Relapses are common if corticosteroids are stopped prematurely or tapered too quickly.

Other idiopathic disorders associated with bronchiolitis include **respiratory bronchiolitis,** which is a disorder of small airways in cigarette smokers. It usually occurs without symptoms or physiologic evidence of lung disease. In some patients, however, it can cause diffuse parenchymal infiltrates, a syndrome referred to as respiratory bronchiolitis–associated interstitial lung disease (RB-ILD) and is often considered with desquamative interstitial pneumonia (DIP) to represent the spectrum of the smoking-related interstitial lung diseases. **Diffuse panbronchiolitis** is an idiopathic disorder of respiratory bronchioles, more frequently diagnosed in Japan. Men are affected about twice as often as women, two-thirds are nonsmokers, and most patients have a history of chronic pansinusitis. Marked dyspnea, cough, and sputum production are frequent, and chest examination shows crackles and rhonchi. Pulmonary function tests reveal obstructive abnormalities, and the chest radiograph shows a distinct pattern of diffuse, small, nodular shadows with hyperinflation.

It is important to consider both the clinical and pathologic classification schemes when evaluating bronchiolitis. Both "constrictive" and "proliferative" pathology can be seen in postinfectious and connective tissue diseases, and integration with the clinical history is important. Compared with constrictive bronchiolitis, proliferative bronchiolitis is overall more common, more likely to show a restrictive or mixed ventilatory defect, more likely to have an abnormal chest radiograph, and more likely to be responsive to corticosteroids. Constrictive bronchiolitis is relatively infrequent but can be seen in a variety of inhalation disorders; hypersensitivity pneumonitis; and chronic rejection in heart-lung, lung, and bone marrow transplant recipients. There is often an obstructive defect with hyperinflation, and chest radiographs may be normal or show hyperinflation. Constrictive bronchiolitis is relatively unresponsive to corticosteroids and is frequently progressive. For both constrictive and proliferative bronchiolitis, open or thoracoscopic lung biopsy is required to make the definitive diagnosis in the majority of cases.

Pneumonia

Lower respiratory tract infections continue to be a major health problem despite advances in the identification of etiologic organisms and the availability of potent antimicrobial drugs. In addition, there is still much controversy regarding optimal diagnostic approaches and treatment choices for pneumonia.

Characteristics of pneumonia caused by specific agents and appropriate antimicrobial therapy are presented in Table 9–9. Pneumonias are typically classified as being either community-acquired or health care-associated. Anaerobic pneumonias and lung abscess can occur in both settings and warrant separate consideration.

Table 9–9. Characteristics and treatment of selected pneumonias.

Organism; Appearance on Smear of Sputum	**Clinical Setting**	**Complications**	**Laboratory Studies**	**Antimicrobial Therapy[1,2]**
Streptococcus pneumoniae	Chronic cardiopulmonary disease;	Bacteremia, meningitis,	Gram stain and culture of sputum, blood, pleural fluid	Preferred[3]: Penicillin G,

(pneumococcus). Gram-positive diplococci (see micrograph); (see micrograph).	follows upper respiratory tract infection	endocarditis, pericarditis, empyema		amoxicillin.
				Alternative: Macrolides, cephalosporins, doxycycline, fluoroquinolones, clindamycin, vancomycin, TMP-SMZ, linezolid.
Haemophilus influenzae. Pleomorphic gram-negative	Chronic cardiopulmonary disease; follows upper respiratory tract	Empyema, endocarditis	Gram stain and culture of sputum, blood, pleural fluid	Preferred[3]: Cefotaxime, ceftriaxone, cefuroxime,

coccobacilli (see micrograph).	infection			doxycycline, azithromycin, TMP-SMZ.
				Alternative: Fluoroquinolones, clarithromycin.
Staphylococcus aureus. Plump gram-positive cocci in clumps.	Residence in chronic care facility, health care–associated, influenza epidemics; cystic fibrosis, bronchiectasis, injection drug use	Empyema, cavitation	Gram stain and culture of sputum, blood, pleural fluid	For methicillin-susceptible strains:
				Preferred: A penicillinase-resistant penicillin with or without rifampin, or

				gentamicin.
				Alternative: A cephalosporin; clindamycin, TMP-SMZ, vancomycin, a fluoroquinolone.
				For methicillin-resistant strains:
				Vancomycin with or without gentamicin or rifampin, linezolid.
Klebsiell	Alcohol	Cavitati	Gram stain	Preferred:

a pneumoniae. Plump gram-negative encapsulated rods (see micrograph).	abuse, diabetes mellitus; health care–associated	on, empyema	and culture of sputum, blood, pleural fluid	Third-generation cephalosporin. For severe infections, add an aminoglycoside.
				Alternative: Aztreonam, imipenem, meropenem, -lactam/ -lactamase inhibitor, an aminoglycoside, or a fluoroqui

				nolone.
Escherichia coli. Gram-negative rods.	Health care–associated; rarely, community-acquired	Empyema	Gram stain and culture of sputum, blood, pleural fluid	Same as for *Klebsiella pneumoniae*.
Pseudomonas aeruginosa. Gram-negative rods.	Health care–associated; cystic fibrosis, bronchiectasis	Cavitation	Gram stain and culture of sputum, blood	Preferred: An antipseudomonal -lactam plus an aminoglycoside.
				Alternative: Ciprofloxacin plus an aminoglycoside or an antipseudomonal

				-lactam.
Anaerobes. Mixed flora.	Aspiration, poor dental hygiene	Necrotizing pneumonia, abscess, empyema	Culture of pleural fluid or of material obtained by transtracheal or transthoracic aspiration	Preferred: Clindamycin, -lactam/ -lactamase inhibitor, imipenem.
Mycoplasma pneumoniae. PMNs and monocytes; no bacteria.	Young adults; summer and fall	Skin rashes, bullous myringitis; hemolytic anemia	PCR. Culture.[4] Complement fixation titer.[5] Cold agglutinin serum titers are not helpful as they lack sensitivity and specificity.	Preferred: Doxycycline or erythromycin. Alternative: Clarithromycin; azithromycin, or a fluoroquinolone.
Legionella	Summer and fall;	Empyema,	Direct immunofl	Preferred: A

species. Few PMNs; no bacteria.	exposure to contaminated construction site, water source, air conditioner; community-acquired or health care–associated	cavitation, endocarditis, pericarditis	uorescent examination or PCR of sputum or tissue; culture of sputum or tissue.[4] Urinary antigen assay for *L pneumophila* serogroup 1.	macrolide with or without rifampin; a fluoroquinolone. Alternative: Doxycycline with or without rifampin, TMP-SMZ.
Chlamydophila pneumoniae. Nonspecific.	Clinically similar to *M pneumoniae*, but prodromal symptoms last longer (up to 2 weeks). Sore throat	Reinfection in older adults with underlying COPD or heart failure may be	Isolation of the organism is very difficult. Serologic studies include microimmunofluorescence with TWAR antigen. PCR at selected	Preferred: Doxycycline. Alternative: Erythromycin, clarithromycin, azithromycin, or a

	with hoarseness common. Mild pneumonia in teenagers and young adults.	severe or even fatal	laboratories.	fluoroquinolone.
Moraxella catarrhalis. Gram-negative diplococci (see micrograph).	Preexisting lung disease; elderly; corticosteroid or immunosuppressive therapy	Rarely, pleural effusions and bacteremia	Gram stain and culture of sputum, blood, pleural fluid	Preferred: A second- or third-generation cephalosporin; a fluoroquinolone.
				Alternative: TMP-SMZ, amoxicillin-clavulanic acid, or a macrolide.

Pneumocystis jiroveci. Nonspecific.	AIDS, immunosuppressive or cytotoxic drug therapy, cancer	Pneumothorax, respiratory failure, ARDS, death	Methenamine silver, Giemsa, or DFA stains of sputum or bronchoalveolar lavage fluid	Preferred: TMP-SMZ or pentamidine isethionate plus prednisone.
				Alternative: Dapsone plus trimethoprim; clindamycin plus primaquine; trimetrexate plus folinic acid.

[1] Antimicrobial sensitivities should guide therapy when available. (Modified from: The choice of antibacterial

drugs. Med Lett Drugs Ther. 2001 Aug 20;43(1111-1112):69–78. [PMID: 11518876] , and from Bartlett JG et al. Practice guidelines for the management of community-acquired pneumonia in adults. Clin Infect Dis. 2000 Aug;31(2):347–82. [PMID: 10987697])

This section sets forth the evaluation and management of pulmonary infiltrates in immunocompetent hosts separately from the approach to immunocompromised hosts—defined as patients with HIV disease, absolute neutrophil counts < 1000/mcL, current or recent exposure to myelosuppressive or immunosuppressive drugs, or those currently taking prednisone in a dosage of over 5 mg/d.

Community-Acquired Pneumonia

Essentials of Diagnosis

- Symptoms and signs of an acute lung infection: fever or hypothermia, cough with or without sputum, dyspnea, chest discomfort, sweats, or rigors.
- Bronchial breath sounds or rales are frequent auscultatory findings.

- Parenchymal infiltrate on chest radiograph.
- Occurs outside of the hospital or less than 48 hours after admission in a patient who is not hospitalized or residing in a long-term care facility.

General Considerations

Community-acquired pneumonia is a common disorder, with approximately 2–3 million cases diagnosed each year in the United States. It is the most deadly infectious disease in the United States and the sixth leading cause of death. Mortality is estimated to be approximately 14% among hospitalized patients and less than 1% for patients who do not require hospitalization. Important risk factors for increased morbidity and mortality from community-acquired pneumonia include advanced age, alcoholism, comorbid medical conditions, altered mental status, respiratory rate 30 breaths/min, hypotension (defined by systolic blood pressure < 90 mm Hg or diastolic blood pressure < 60 mm Hg), and increased blood urea nitrogen (BUN).

In immunocompetent patients, the history, physical examination, radiographs, and sputum examination are neither sensitive nor specific for identifying the microbiologic cause of community-acquired pneumonia. While helpful in selected patients, these modalities do not consistently differentiate bacterial from viral causes or distinguish "typical" from "atypical" causes. As a result, the American Thoracic Society and Infectious Disease Society of America recommend empiric treatment based on epidemiologic data.

Definition & Pathogenesis

Community-acquired pneumonia is most often diagnosed outside of the hospital in ambulatory patients who are not residents of nursing homes and other long-term care facilities. It may also be diagnosed in a previously ambulatory patient within 48 hours after admission to the hospital.

Pulmonary defense mechanisms (cough reflex, mucociliary clearance system, immune responses) normally prevent the development of lower respiratory tract infections following aspiration of oropharyngeal secretions containing bacteria or inhalation of infected aerosols. Community-acquired pneumonia occurs when there is a defect in one or more of the normal host defense mechanisms or when a very large infectious inoculum or a highly virulent pathogen overwhelms the host.

Prospective studies have failed to identify the cause of community-acquired pneumonia in 40–60% of cases; two or more causes are identified in up to 5% of cases. Bacteria are more commonly identified than viruses. The most common bacterial pathogen identified in most studies of community-acquired pneumonia is *S* *pneumoniae*, accounting for approximately two-thirds of bacterial isolates. Other common bacterial pathogens include *H influenzae, M pneumoniae, C pneumoniae, S aureus, Neisseria meningitidis, M catarrhalis, Klebsiella pneumoniae*, other gram-negative rods, and *Legionella* species. Common viral causes of community-acquired pneumonia include influenza virus, respiratory syncytial virus, adenovirus, and parainfluenza virus. A detailed assessment of epidemiologic risk factors may aid in diagnosing pneumonias due to the following causes: *Chlamydia psittaci* (psittacosis), *Coxiella burnetii* (Q fever), *Francisella tularensis* (tularemia), endemic fungi (*Blastomyces, Coccidioides, Histoplasma*), and sin nombre virus (hantavirus pulmonary syndrome).

Clinical Findings

Symptoms and Signs

Most patients with community-acquired pneumonia experience an acute or subacute onset of fever, cough with or without sputum production, and dyspnea. Other common symptoms include rigors, sweats, chills, chest discomfort, pleurisy, hemoptysis, fatigue, myalgias, anorexia, headache, and abdominal pain.

Common physical findings include fever or hypothermia, tachypnea, tachycardia, and mild arterial oxygen desaturation. Many patients will appear acutely ill. Chest examination is often remarkable for altered breath sounds and rales . Dullness to percussion may be present if a parapneumonic pleural effusion is present.

The differential diagnosis of lower respiratory tract symptoms and signs is extensive and includes upper respiratory tract infections, reactive airway diseases, congestive heart failure, COP, lung cancer, pulmonary vasculitis, pulmonary thromboembolic disease, and atelectasis.

Laboratory Findings

Controversy surrounds the role of Gram stain and culture analysis of expectorated sputum in patients with community-acquired pneumonia. Most reports suggest that these tests have poor positive and negative predictive value in most patients. Some argue, however, that the tests should still be performed to try to identify etiologic organisms in the hope of reducing microbial resistance to drugs, unnecessary drug costs, and avoidable side effects of empiric antibiotic therapy. Expert panel guidelines suggest that sputum Gram stain should be attempted in all patients with community-acquired pneumonia and that sputum culture should be obtained for all patients who require hospitalization. Sputum should be obtained before antibiotics are initiated except in a case of suspected antibiotic failure. The specimen is obtained by deep cough and should be grossly purulent. Culture should be performed only if the specimen meets strict cytologic criteria, eg, more than 25 neutrophils and fewer than 10 squamous epithelial cells per low power field. There criteria do not apply to cultures of legionalla or mycobacteria.

Additional testing is generally recommended for patients who require hospitalization: preantibiotic blood cultures (at least two sets with needle sticks at separate sites), arterial blood gases, complete blood count with differential, and a chemistry panel (including serum glucose, electrolytes, urea nitrogen, creatinine, bilirubin, and liver enzymes). The results of these tests help assess the severity of the disease and guide evaluation and therapy. HIV testing should be considered in all adult patients, and performed in those with risk factors.

Imaging

Chest radiography may confirm the diagnosis and detect associated lung diseases. It can also be used to help assess severity and response to therapy over time. Radiographic findings can range from patchy airspace infiltrates to lobar consolidation with air bronchograms to diffuse alveolar or interstitial infiltrates (see x-ray). Additional findings can include pleural effusions and cavitation (see x-ray). No pattern of radiographic abnormalities is pathognomonic of a specific cause of pneumonia.

Fig.

Haemophilus influenzae pneumonia. A diffuse, ill-defined, poorly marginated infiltrate occupies the upper portion of the left lung, radiating from the hilum to the periphery. There is no obvious associated mediastinal adenopathy, nor is there any pleural effusion. This ill-defined picture without significant change in lung volume is frequently seen with *Haemophilus influenzae* pneumonia. (Courtesy of H Goldberg.)

Fig.

Cavitary pneumonia. Posteroanterior ***(A)*** and lateral ***(B)*** chest radiographs demonstrate consolidation with cavitation (*arrows*) in the superior segment of the left lower lobe secondary to *Pseudomonas* pneumonia. A small left pleural effusion is present, best seen on the lateral view (*arrowhead*). Changes of chronic obstructive pulmonary disease are present. (Reproduced, with permission, from Bongard FS, Sue DY [editors]: *Current*

Critical Care Diagnosis & Treatment. Originally published by Appleton & Lange. Copyright © 1994 by The McGraw-Hill Companies, Inc.)

Progression of pulmonary infiltrates during antibiotic therapy or lack of radiographic improvement over time are poor prognostic signs and also raise concerns about secondary or alternative pulmonary processes. Clearing of pulmonary infiltrates in patients with community-acquired pneumonia can take 6 weeks or longer and is usually fastest in young patients, nonsmokers, and those with only single lobe involvement.

Special Examinations

Sputum induction is reserved for patients who cannot provide expectorated sputum samples or who may have *P jiroveci* or *Mycobacterium tuberculosis* pneumonia. Transtracheal aspiration, fiberoptic bronchoscopy, and transthoracic needle aspiration techniques to obtain samples of lower respiratory secretions or tissues are reserved for selected patients.

Thoracentesis with pleural fluid analysis (Gram stain and cultures; glucose, lactate dehydrogenase (LD), and total protein levels; leukocyte count with differential; pH determination) should be performed on most patients with pleural effusions to assist in diagnosis of the etiologic agent and assess for empyema or complicated parapneumonic process. Serologic assays, polymerase chain reaction tests, specialized culture tests, and other new diagnostic tests for organisms such as *Legionella*,*M pneumoniae*, and *C pneumoniae* are performed when these diagnoses are suspected. Limitations of many of these tests include delay in obtaining test results and poor sensitivity and specificity.

Treatment

Antimicrobial therapy should be initiated promptly after the diagnosis of pneumonia is established and appropriate specimens are obtained, especially in patients who require hospitalization. Delays in obtaining diagnostic specimens or the results of testing should not preclude the early administration of antibiotics to acutely ill patients. Decisions regarding hospitalization should be based on prognostic criteria as outlined above in the section on general considerations. Treatment recommendations can be divided into those for patients who can be treated as outpatients and those for patients who require hospitalization.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Special consideration must be given to penicillin-resistant strains of *S pneumoniae* strains to penicillin. Intermediate resistance to penicillin is defined as a minimum inhibitory concentration (MIC) of 0.1–1 mcg/mL. Strains with high-level resistance usually require an MIC 2 mcg/mL for penicillin. Resistance to other antibiotics (beta-lactams, trimethoprim-sulfamethoxazole, macrolides, others) often accompanies resistance to penicillin. The prevalence of resistance varies by patient group, geographic region, and over time. Local resistance pattern data should therefore guide empiric therapy of suspected or documented *S pneumoniae* infections until specific susceptibility test results are available.

Treatment of Outpatients

Empiric antibiotic options for patients with community-acquired pneumonia who do not require hospitalization include the following: (1) Macrolides (clarithromycin, 500 mg orally twice a day, or azithromycin, 500 mg orally as a first dose and then 250 mg once a day for 4 days, or 500 mg daily for 3 days). (2) Doxycycline (100 mg orally twice a day). (3) Fluoroquinolones (with enhanced activity against *S pneumoniae*, such as levofloxacin 500 mg orally once a day, or moxifloxacin 400 mg orally once a day). Some experts prefer doxycycline or macrolides for patients under 50 years of age without comorbidities and a fluoroquinolone for patients with comorbidities or who are older than 50 years of age. Alternatives include erythromycin (250–500 mg orally four times daily), amoxicillin-potassium clavulanate—especially for suspected aspiration pneumonia—500 mg orally three times a day or 875 mg orally twice a day, and some second- and third-generation cephalosporins such as cefuroxime axetil (250–500 mg orally twice a day), cefpodoxime proxetil (100–200 mg orally twice a day), or cefprozil (250–500 mg orally twice a day).

There are limited data to guide recommendations for duration of treatment. The decision is influenced by the severity of illness, the etiologic agent, response to therapy, other medical problems, and complications. Therapy until the patient is afebrile for at least 72 hours is usually sufficient for pneumonia due to *S pneumoniae.* A minimum of 2 weeks of therapy is appropriate for pneumonia due to *S aureus, P aeruginosa, Klebsiella,* anaerobes, *M pneumoniae, C pneumoniae,* or *Legionella* species.

Treatment of Hospitalized Patients

Empiric antibiotic options for patients with community-acquired pneumonia who require hospitalization can be divided into those for patients who can be cared for on a general medical ward and those for patients who require care in an ICU. Patients who only require general medical ward care usually respond to an extended-spectrum -lactam (such as ceftriaxone or cefotaxime) with a macrolide (clarithromycin or azithromycin is preferred if *H influenzae* infection is suspected) or a fluoroquinolone (with enhanced activity against *S pneumoniae*) such as levofloxacin or moxifloxacin. Alternatives include a -lactam/ -lactamase inhibitor (ampicillin-sulbactam or piperacillin-tazobactam) with a macrolide.

Patients requiring admission to the ICU require a macrolide or a fluoroquinolone (with enhanced activity against *S pneumoniae*) plus an extended-spectrum cephalosporin (ceftriaxone, cefotaxime) or a -lactam/ -lactamase inhibitor (ampicillin-sulbactam or piperacillin-tazobactam). Patients with penicillin allergies can be treated with a fluoroquinolone (with enhanced activity against *S pneumoniae*) with or without clindamycin. Patients with suspected aspiration pneumonia should receive a fluoroquinolone (with enhanced activity against *S pneumoniae*) with or without clindamycin, metronidazole, or a -lactam/ -lactamase inhibitor. Patients with structural lung diseases such as bronchiectasis or cystic fibrosis benefit from empiric therapy with an antipseudomonal penicillin, carbapenem, or cefepime plus a fluoroquinolone (including high-dose ciprofloxacin) until sputum culture and sensitivity results are available. For expanded discussions of specific antibiotics, see Chapter 30: Common Problems in Infectious Diseases & Antimicrobial Therapy.

Almost all patients who are admitted to a hospital for therapy of community-acquired pneumonia receive intravenous antibiotics. Despite this preference, no studies demonstrate superior outcomes when hospitalized patients are treated intravenously instead of orally if patients can tolerate oral therapy and the drug is well absorbed. Duration of antibiotic treatment is the same as for outpatients with community-acquired pneumonia.

Prevention

Polyvalent pneumococcal vaccine (containing capsular polysaccharide antigens of 23 common strains of *S pneumoniae*) has the potential to prevent or lessen the severity of the majority of pneumococcal infections in immunocompetent patients. Indications for pneumococcal vaccination include the following: age 65 years or any chronic illness that increases the risk of community-acquired pneumonia (see Chapter 30: Common Problems in Infectious Diseases & Antimicrobial Therapy). Immunocompromised patients and those at highest risk of fatal pneumococcal infections should receive a single revaccination 6 years after the first vaccination. Immunocompetent persons 65 years of age or older should receive a second dose of vaccine if the patient first received the vaccine 6 or more years previously and was under 65 years old at the time of vaccination.

The influenza vaccine is effective in preventing severe disease due to influenza virus with a resulting positive impact on both primary influenza pneumonia and secondary bacterial pneumonias. The influenza vaccine is administered annually to persons at risk for complications of influenza infection (age 65 years, residents of long-term care facilities, patients with pulmonary or cardiovascular disorders, patients recently hospitalized with chronic metabolic disorders) as well as health care workers and others who are able to transmit influenza to high-risk patients.

Hospitalized patients who would benefit from pneumococcal and influenza vaccines should be vaccinated during hospitalization. The vaccines can be given simultaneously, and there are no contraindications to use immediately after an episode of pneumonia.

When To Admit

- Failure of outpatient therapy, including inability to maintain oral intake and medications.
- Exacerbations of underlying disease that would benefit from hospitalization.
- Complications of pneumonia (such as hypoxemia, pleural effusion, sepsis, encephalopathy).
- Other medical or psychosocial needs (such as cognitive dysfunction, psychiatric disease, homelessness, drug abuse, lack of outpatient resources, or poor overall functional status).

Health Care–Associated Pneumonia

Essentials of Diagnosis

- Occurs more than 48 hours after admission to the hospital or other health care facility and excludes any infection present at the time of admission.
- At least two of the following: fever, cough, leukocytosis, purulent sputum.
- New or progressive parenchymal infiltrate on chest radiograph.
- Especially common in patients requiring intensive

care or mechanical ventilation.

General Considerations

Health care–associated pneumonia is an important cause of morbidity and mortality despite widespread use of preventive measures, advances in diagnostic testing, and potent new antimicrobial agents. Health care–associated pneumonia is the second most common cause of infection among hospital inpatients and is the leading cause of death due to infection with mortality rates ranging from 20% to 50%. While the majority of cases occur in patients who are not in an ICU, the highest-risk patients are those in such units or who are being mechanically ventilated; these patients also experience higher morbidity and mortality from health care-associated pneumonias.

Definition & Pathogenesis

Health care–associated pneumonia is defined as pneumonia developing more than 48 hours after admission to the hospital or other health care facility. Ventilator-associated pneumonia develops in a mechanically ventilated patient more than 48 hours after intubation.

Colonization of the pharynx and possibly the stomach with bacteria is the most important step in the pathogenesis of health care–associated pneumonia. Pharyngeal colonization is promoted by exogenous factors (instrumentation of the upper airway with nasogastric and endotracheal tubes, contamination by dirty hands and equipment, and treatment with broad-spectrum antibiotics that promote the emergence of drug-resistant organisms) and patient factors (malnutrition, advanced age, altered consciousness, swallowing disorders, and underlying pulmonary and systemic diseases). Aspiration of infected pharyngeal or gastric secretions delivers bacteria directly to the lower airway. Impaired cellular and mechanical defense mechanisms in the lungs of hospitalized patients raise the risk of infection after aspiration has occurred. Tracheal intubation increases the risk of lower respiratory infection by mechanical obstruction of the trachea, impairment of mucociliary clearance, trauma to the mucociliary escalator system, and interference with coughing. Tight adherence of bacteria such as *Pseudomonas* to the tracheal epithelium and the biofilm that lines the endotracheal tube makes clearance of these organisms from the lower airway difficult. Less important pathogenetic mechanisms of health care–associated pneumonia include inhalation of contaminated aerosols and hematogenous dissemination of microorganisms.

The role of the stomach in the pathogenesis of health care–associated pneumonia remains controversial. Observational studies have suggested that elevation of gastric pH due to antacids, H_2-receptor antagonists, or enteral feeding is associated with gastric microbial overgrowth, tracheobronchial colonization, and health care–associated pneumonia. Sucralfate, a cytoprotective agent that does not alter gastric pH, is associated with a trend toward a lower incidence of ventilator-associated pneumonia.

The most common organisms responsible for health care–associated pneumonia are *P aeruginosa, S aureus*, *Enterobacter*,*K pneumoniae*, and *Escherichia coli*.*Proteus*,*Serratia marcescens, H influenzae*, and streptococci account for most of the remaining cases. Infection by *P aeruginosa* and *Acinetobacter* tend to cause pneumonia in the most debilitated patients, those with previous antibiotic therapy, and those requiring mechanical ventilation. Anaerobic organisms (bacteroides, anaerobic streptococci, fusobacterium) may also cause pneumonia in the hospitalized patient; when isolated, they are commonly part of a polymicrobial flora. Mycobacteria, fungi, chlamydiae, viruses, rickettsiae, and protozoal organisms are uncommon causes of health care–associated pneumonia.

Clinical Findings

Symptoms and Signs

The symptoms and signs associated with health care–associated pneumonia are nonspecific; however, one or more clinical findings (fever, leukocytosis, purulent sputum, and a new or progressive pulmonary infiltrate on chest radiograph) are present in most patients. Other findings associated with health care–associated pneumonia include those listed above for community-acquired pneumonia.

The differential diagnosis of new lower respiratory tract symptoms and signs in hospitalized patients includes congestive heart failure, atelectasis, aspiration, ARDS, pulmonary thromboembolism, pulmonary hemorrhage, and drug reactions.

Laboratory Findings

The minimum evaluation for suspected health care–associated pneumonia includes blood cultures from two different sites and an arterial blood gas or pulse oximetry determination. Blood cultures can identify the pathogen in up to 20% of all patients with health care–associated pneumonia; positivity is associated with increased risk for complications and other sites of infection. The assessment of oxygenation helps define the severity of illness and determines the need for supplemental oxygen. Blood counts and clinical chemistry tests are not helpful in establishing a specific diagnosis of health care–associated pneumonia; however, they can help define the severity of illness and identify complications. Thoracentesis for pleural fluid analysis (stains, cultures; glucose, LD, and total protein levels; leukocyte count with differential; pH determination) should be performed in patients with pleural effusions.

Examination of sputum is attended by the same disadvantages as in community-acquired pneumonia. Gram stains and cultures of sputum are neither sensitive nor specific in the diagnosis of health care–associated pneumonia. The identification of a bacterial organism by culture of sputum does not prove that the organism is a lower respiratory tract pathogen. However, it can be used to help identify antibiotic sensitivity patterns of bacteria and as a guide to therapy. If health care–associated pneumonia from *Legionella pneumophila* is suspected, direct fluorescent antibody staining can be performed. Sputum stains and cultures for mycobacteria and certain fungi may be diagnostic.

Imaging

Radiographic findings are nonspecific and can range from patchy airspace infiltrates to lobar consolidation with air bronchograms to diffuse alveolar or interstitial infiltrates. Additional findings can include pleural effusions and cavitation. Progression of pulmonary infiltrates during antibiotic therapy and lack of radiographic improvement over time are poor prognostic signs and also raise concerns about secondary or alternative pulmonary processes. Clearing of pulmonary infiltrates can take 6 weeks or longer.

Special Examinations

Endotracheal aspiration using a sterile suction catheter and fiberoptic bronchoscopy with bronchoalveolar lavage or a protected specimen brush can be used to obtain lower respiratory tract secretions for analysis, most commonly in patients with ventilator-associated pneumonias. Endotracheal aspiration cultures have significant negative predictive value but limited positive predictive value in the diagnosis of specific etiologic agents in patients with health care–associated pneumonia. An invasive diagnostic approach using quantitative culture of bronchoalveolar lavage samples or protected specimen brush samples in patients suspected of having ventilator-associated pneumonia leads to significantly less antibiotic use, earlier attenuation of organ dysfunction, and fewer deaths at 14 days.

Treatment

Treatment of health care–associated pneumonia, like treatment of community-acquired pneumonia, is usually empiric. Because of the high mortality rate, therapy should be started as soon as pneumonia is suspected. Initial regimens must be broad in spectrum and tailored to the specific clinical setting. There is no uniform consensus on the best regimens.

Recommendations for the treatment of health care–associated pneumonia have been proposed by many organizations, including the American Thoracic Society. Initial empiric therapy with antibiotics is determined by the severity of illness, risk factors, and the length of hospitalization. Empiric therapy for mild to moderate health care–associated pneumonia in a patient without unusual risk factors or a patient with severe early-onset (within 5 days after admission) health care–associated pneumonia may consist of a second-generation cephalosporin, a non-antipseudomonal third-generation cephalosporin, or a combination of a -lactam and -lactamase inhibitor.

Empiric therapy for patients with severe, late-onset (5 days after admission) health care–associated pneumonia or with ICU- or ventilator-associated pneumonia should include a combination of antibiotics directed against the most virulent organisms, particularly *P aeruginosa*, *Acinetobacter* species, and *Enterobacter* species. The antibiotic regimen should include an aminoglycoside or fluoroquinolone plus one of the following: an antipseudomonal penicillin, an antipseudomonal cephalosporin, a carbapenem, or aztreonam—aztreonam alone with an aminoglycoside will be inadequate if coverage for gram-positive organisms or *H influenzae* is required. Vancomycin is added if infection with methicillin-resistant *S aureus* is of concern (especially in patients with coma, head trauma, diabetes mellitus, or advanced chronic kidney disease, or who are in the ICU).

Anaerobic coverage with clindamycin or a -lactam/ -lactamase inhibitor combination may be added for patients who have risk factors for anaerobic pneumonia, including aspiration, recent thoracoabdominal surgery, or an obstructing airway lesion. A macrolide is added when patients are at risk for *Legionella* infection, such as those receiving high-dose corticosteroids. After results of sputum, blood, and pleural fluid cultures have been obtained, it may be possible to switch to a regimen with a narrower spectrum. Duration of antibiotic therapy should be individualized based on the pathogen, severity of illness, response to therapy, and comorbid conditions. Therapy for gram-negative bacterial pneumonia is typically continued for at least 14 days. Data from a large trial assessing treatment outcomes in ventilator-associated pneumonia suggest that 8 days of antibiotics is as good as 15 days, except in cases caused by *P aeruginosa*.

Anaerobic Pneumonia & Lung Abscess

Essentials of Diagnosis

- History of or predisposition to aspiration.
- Indolent symptoms, including fever, weight loss, malaise.
- Poor dentition.
- Foul-smelling purulent sputum (in many patients).
- Infiltrate in dependent lung zone, with single or multiple areas of cavitation or pleural effusion.

General Considerations

Aspiration of small amounts of oropharyngeal secretions occurs during sleep in normal individuals but rarely causes disease. Sequelae of aspiration of larger amounts of material include nocturnal asthma, chemical pneumonitis, mechanical obstruction of airways by particulate matter, bronchiectasis, and pleuropulmonary infection. Individuals predisposed to disease induced by aspiration include those with depressed levels of consciousness due to drug or alcohol use, seizures, general anesthesia, or central nervous system disease; those with impaired deglutition due to esophageal disease or neurologic disorders; and those with tracheal or nasogastric tubes, which disrupt the mechanical defenses of the airways.

Periodontal disease and poor dental hygiene, which increase the number of anaerobic bacteria in aspirated material, are associated with a greater likelihood of anaerobic pleuropulmonary infection. Aspiration of infected oropharyngeal contents initially leads to pneumonia in dependent lung zones, such as the posterior segments of the upper lobes and superior and basilar segments of the lower lobes. Body position at the time of aspiration determines which lung zones are dependent. The onset of symptoms is insidious. By the time the patient seeks medical attention, necrotizing pneumonia, lung abscess, or empyema may be apparent.

Most aspiration patients with necrotizing pneumonia, lung abscess, and empyema are found to be infected with multiple species of anaerobic bacteria. Most of the remainder are infected with both anaerobic and aerobic bacteria. *Prevotella melaninogenica, Peptostreptococcus,* *Fusobacterium nucleatum*, and *Bacteroides* species are commonly isolated anaerobic bacteria.

Clinical Findings

Symptoms and Signs

Patients with anaerobic pleuropulmonary infection usually present with constitutional symptoms such as fever, weight loss, and malaise. Cough with expectoration of foul-smelling purulent sputum suggests anaerobic infection, though the absence of productive cough does not rule out such an infection. Dentition is often poor. Patients are rarely edentulous; if so, an obstructing bronchial lesion is usually present.

Laboratory Findings

Expectorated sputum is inappropriate for culture of anaerobic organisms because of contaminating mouth flora. Representative material for culture can be obtained only by transthoracic aspiration, thoracentesis, or bronchoscopy with a protected brush. Transthoracic aspiration is rarely indicated, because drainage occurs via the bronchus and anaerobic pleuropulmonary infections usually respond well to empiric therapy.

Imaging

The different types of anaerobic pleuropulmonary infection are distinguished on the basis of their radiographic appearance. **Lung abscess** appears as a thick-walled solitary cavity surrounded by consolidation (see x-ray); (see x-ray). An air-fluid level is usually present. Other causes of cavitary lung disease (tuberculosis, mycosis, cancer, infarction, Wegener granulomatosis) should be excluded. **Necrotizing pneumonia** is distinguished by multiple areas of cavitation within an area of consolidation. **Empyema** is characterized by the presence of purulent pleural fluid and may accompany either of the other two radiographic findings (see CT scan). Ultrasonography is of value in locating fluid and may also reveal pleural loculations.

Fig.

Abscess in the left upper lobe of the lung. The large, irregularly marginated lesion with a central air collection represents an abscess. In contrast to a pneumatocele, which has sharp, thin walls, this has a thick, shaggy wall indicative of abscess or cavitating tumor. (Courtesy of H Goldberg.)

Treatment

Penicillins have been the standard treatment for anaerobic pleuropulmonary infections. However, an increasing number of anaerobic organisms produce -lactamases, and up to 20% of patients do not respond to penicillins. Improved responses have been documented with clindamycin (600 mg intravenously every 8 hours until improvement, then 300 mg orally every 6 hours) or amoxicillin-clavulanate (875 mg orally every 12 hours). Penicillin (amoxicillin, 500 mg every 8 hours, or penicillin G, 1–2 million units intravenously every 4–6 hours) plus metronidazole (500 mg orally or intravenously every 8–12 hours) is another option. Antibiotic therapy should be continued until the chest radiograph improves, a process that may take a month or more; patients with lung abscesses should be treated until radiographic resolution of the abscess cavity is demonstrated. Anaerobic pleuropulmonary disease requires adequate drainage with tube thoracostomy for the treatment of empyema. Open pleural drainage is sometimes necessary because of the propensity of these infections to produce loculations in the pleural space.

Pulmonary Infiltrates in the Immunocompromised Host

Pulmonary infiltrates in immunocompromised patients may arise from infectious or noninfectious causes. Infection may be due to bacterial, mycobacterial, fungal, protozoal, helminthic, or viral pathogens. Noninfectious processes such as pulmonary edema, alveolar hemorrhage, drug reactions, pulmonary thromboembolic disease, malignancy, and radiation pneumonitis may mimic infection.

Although almost any pathogen can cause pneumonia in a compromised host, two clinical tools help the clinician narrow the differential diagnosis. The first is knowledge of the underlying immunologic defect. Specific immunologic defects are associated with particular infections. Defects in humoral immunity predispose to bacterial infections; defects in cellular immunity lead to infections with viruses, fungi, mycobacteria, and protozoa. Neutropenia and impaired granulocyte function predispose to infections from *S aureus*, *Aspergillus*, gram-negative bacilli, and *Candida*. Second, the time course of infection also provides clues to the etiology of pneumonia in immunocompromised patients. A fulminant pneumonia is often caused by bacterial infection, whereas an insidious pneumonia is more apt to be caused by viral, fungal, protozoal, or mycobacterial infection. Pneumonia occurring within 2–4 weeks after organ transplantation is usually bacterial, whereas several months or more after transplantation *P jiroveci*, viruses (eg, cytomegalovirus), and fungi (eg, *Aspergillus*) are encountered more often.

Chest radiography is rarely helpful in narrowing the differential diagnosis. Examination of expectorated sputum for bacteria, fungi, mycobacteria, *Legionella,* and *P jiroveci* is important and may preclude the need for expensive, invasive diagnostic procedures. Sputum induction is often necessary for diagnosis. The sensitivity of induced sputum for detection of *P jiroveci* depends on institutional expertise, number of specimens analyzed, and detection methods.

Routine evaluation frequently fails to identify a causative organism. The clinician may begin empiric antimicrobial therapy and proceed to invasive procedures such as bronchoscopy, transthoracic needle aspiration, or open lung biopsy. The approach to management must be based on the severity of the pulmonary infection, the underlying disease, the risks of empiric therapy, and local expertise and experience with diagnostic procedures. Bronchoalveolar lavage using the flexible bronchoscope is a safe and effective method for obtaining representative pulmonary secretions for microbiologic studies. It involves less risk of bleeding and other complications than bronchial brushing and transbronchial biopsy. Bronchoalveolar lavage is especially suitable for the diagnosis of *P jiroveci* pneumonia in patients with AIDS when induced sputum analysis is negative. Surgical lung biopsy, now often performed by video-assisted thoracoscopy, provides the best opportunity for diagnosis of pulmonary infiltrates in the immunocompromised host. However, a specific diagnosis is obtained in only about two-thirds of cases, and the information obtained rarely affects the outcome. Therefore, empiric treatment is often preferred.

Pulmonary Tuberculosis

Essentials of Diagnosis

- Fatigue, weight loss, fever, night sweats, and cough.
- Pulmonary infiltrates on chest radiograph, most often apical.
- Positive tuberculin skin test reaction (most cases).
- Acid-fast bacilli on smear of sputum or sputum culture positive for *M tuberculosis*.

General Considerations

Tuberculosis is one of the world's most widespread and deadly illnesses. *M tuberculosis*, the organism that causes tuberculosis infection and disease, infects an estimated 20–43% of the world's population. Each year, 3 million people worldwide die of the disease. In the United States, it is estimated that 15 million people are infected with *M tuberculosis*. Tuberculosis occurs disproportionately among disadvantaged populations such as the malnourished, homeless, and those living in overcrowded and substandard housing. There is an increased occurrence of tuberculosis among HIV-positive individuals.

Infection with *M tuberculosis* begins when a susceptible person inhales airborne droplet nuclei containing viable organisms. Tubercle bacilli that reach the alveoli are ingested by alveolar macrophages. Infection follows if the inoculum escapes alveolar macrophage microbicidal activity. Once infection is established, lymphatic and hematogenous dissemination of tuberculosis typically occurs before the development of an effective immune response. This stage of infection, **primary tuberculosis**, is usually clinically and radiographically silent. In most persons with intact cell-mediated immunity, T cells and macrophages surround the organisms in granulomas that limit their multiplication and spread. The infection is contained but not eradicated, since viable organisms may lie dormant within granulomas for years to decades.

Individuals with this **latent tuberculosis infection** do not have active disease and cannot transmit the organism to others. However, reactivation of disease may occur if the host's immune defenses are impaired. Active tuberculosis will develop in approximately 10% of individuals with latent tuberculosis infection who are not given preventive therapy; half of these cases occur in the 2 years following primary infection. Up to 50% of HIV-infected patients will develop active tuberculosis within 2 years after infection with tuberculosis. Diverse conditions such as gastrectomy, silicosis, diabetes mellitus, and disorders associated with immunosuppression (eg, HIV infection or therapy with corticosteroids or other immunosuppressive drugs) are associated with an increased risk of reactivation.

In approximately 5% of cases, the immune response is inadequate and the host develops **progressive primary tuberculosis**, accompanied by both pulmonary and constitutional symptoms that are described below. Standard teaching has held that 90% of tuberculosis in adults represents activation of latent disease. New diagnostic technologies such as DNA fingerprinting suggest that as many as one-third of new cases of tuberculosis in urban populations are primary infections resulting from person-to-person transmission.

The percentage of patients with atypical presentations—particularly elderly patients, patients with HIV infection, and those in nursing homes—has increased. Extrapulmonary tuberculosis is especially common in patients with HIV infection, who often display lymphadenitis or miliary disease (see x-ray).

Fig.

Miliary tuberculosis. Multiple fine nodular densities are distributed throughout the central and peripheral areas of both lungs. This finely nodular pattern is often called a miliary pattern and is typical of miliary tuberculosis. (Courtesy of H Goldberg.)

Strains of *M tuberculosis* resistant to one or more first-line antituberculous drugs are being encountered with increasing frequency. Risk factors for drug resistance include immigration from parts of the world with a high prevalence of drug-resistant tuberculosis, close and prolonged contact with individuals with drug-resistant tuberculosis, unsuccessful previous therapy, and patient noncompliance. Resistance to one or more antituberculous drugs has been found in 15% of tuberculosis patients in the United States. Outbreaks of multidrug-resistant tuberculosis in hospitals and correctional facilities in Florida and New York have been associated with mortality rates of 70–90% and median survival rates of 4–16 weeks.

Clinical Findings

Symptoms and Signs

The patient with pulmonary tuberculosis typically presents with slowly progressive constitutional symptoms of malaise, anorexia, weight loss, fever, and night sweats. Chronic cough is the most common pulmonary symptom. It may be dry at first but typically becomes productive of purulent sputum as the disease progresses. Blood-streaked sputum is common, but significant hemoptysis is rarely a presenting symptom; life-threatening hemoptysis may occur in advanced disease. Dyspnea is unusual unless there is extensive disease. Rarely, the patient is asymptomatic. On physical examination, the patient appears chronically ill and malnourished. On chest examination, there are no physical findings specific for tuberculosis infection. The examination may be normal or may reveal classic findings such as posttussive apical rales.

Laboratory Findings

Definitive diagnosis depends on recovery of *M tuberculosis* from cultures or identification of the organism by DNA or RNA amplification techniques. Three consecutive morning sputum specimens are advised. Sputum induction may be helpful in patients who cannot voluntarily produce satisfactory specimens. Fluorochrome staining with rhodamine-auramine of concentrated, digested sputum specimens is performed initially as a screening method, with confirmation by the Kinyoun or Ziehl-Neelsen stains. Demonstration of acid-fast bacilli on sputum smear does not confirm a diagnosis of tuberculosis, since saprophytic nontuberculous mycobacteria may colonize the airways and rarely may cause pulmonary disease.

In patients thought to have tuberculosis despite negative sputum smears, fiberoptic bronchoscopy can be considered (see bronchoscopy). Bronchial washings are helpful; however, transbronchial lung biopsies increase the diagnostic yield. Postbronchoscopy expectorated sputum specimens may also be useful. Early morning aspiration of gastric contents after an overnight fast is an alternative to bronchoscopy but is suitable only for culture and not for stained smear, because nontuberculous mycobacteria may be present in the stomach in the absence of tuberculous infection. *M tuberculosis* may be cultured from blood in up to 15% of patients with tuberculosis.

Fig.

Right B^{9}a is stenotic and filled with stones caused by tuberculosis. The stone in this figure was yellowish and was extirpated by biopsy forceps. A small protrusion was observed at the bifurcation of B^{9}a and B^{9}b, where biopsy had been performed 2 weeks previously. (Reproduced, with permission, from Oho K, Amemiya R: *Practical Fiberoptic Bronchoscopy*. Igaku-Shoin, 1980.)

Cultures on solid media to identify *M tuberculosis* may require 12 weeks. Liquid medium culture systems allow detection of mycobacterial growth in several days, although this depends on the number of organisms in the inoculum. The slow rate of mycobacterial growth has fostered interest in rapid diagnostic techniques. Nucleic acid amplification or high-performance liquid chromatography can be used to identify the type of mycobacterium within hours of sputum processing. Rapid confirmation of *M tuberculosis* is valuable in the mobilization of public health resources.

Nucleic acid amplification (DNA and RNA) tests for *M tuberculosis* should be interpreted in the clinical context and on the basis of local laboratory performance. A patient whose sputum culture is positive for acid-fast bacilli but whose nucleic acid amplification test result is negative for *M tuberculosis* may have a false-negative amplification test, a false-positive smear, or a nontuberculous mycobacterial infection. Clinical suspicion remains a critical factor in interpreting these studies. Drug susceptibility testing of culture isolates is considered routine for the first isolate of *M tuberculosis*, when a treatment regimen is failing, and when sputum cultures remain positive after 2 months of therapy.

Needle biopsy of the pleura reveals granulomatous inflammation in approximately 60% of patients with pleural effusions caused by *M tuberculosis.* Pleural fluid cultures for *M tuberculosis* are positive in less than 25% of cases of pleural tuberculosis. Culture of three pleural biopsy specimens combined with microscopic examination of a pleural biopsy yields a diagnosis in up to 90% of patients with pleural tuberculosis.

Imaging

Radiographic abnormalities in primary tuberculosis include small homogeneous infiltrates, hilar and paratracheal lymph node enlargement, and segmental atelectasis (see x-ray). Pleural effusion may be present, especially in adults, sometimes as the sole radiographic abnormality. Cavitation may be seen with progressive primary tuberculosis (Plate 66). Ghon (calcified primary focus) and Ranke (calcified primary focus and calcified hilar lymph node) complexes are seen in a minority of patients and represent residual evidence of healed primary tuberculosis (see illustration).

Fig.

A: Pulmonary tuberculosis. The chest film in this child with primary pulmonary tuberculosis demonstrates a large right hilar mass, the result of enlarged hilar lymph nodes. ***B:*** In the same patient, on the lateral view, the large hilar mass is clearly outlined, with a normal tracheal air column seen above it. (Courtesy of H Goldberg.)

Pulmonary tuberculosis. (Reproduced, with permission, from Chandrasoma P, Taylor CR: *Concise Pathology*, 2nd ed. Originally published by Appleton & Lange. Copyright © 1995 by The McGraw-Hill Companies, Inc.)

Reactivation tuberculosis is associated with various radiographic manifestations, including fibrocavitary apical disease, nodules, and pneumonic infiltrates (see x-ray). The usual location is in the apical or posterior segments of the upper lobes or in the superior segments of the lower lobes; up to 30% of patients may present with radiographic evidence of disease in other locations. This is especially true in elderly patients, in whom lower lobe infiltrates with or without pleural effusion are encountered with increasing frequency. Lower lung tuberculosis may masquerade as pneumonia or lung cancer. A "miliary" pattern (diffuse small nodular densities) (see x-ray) can be seen with hematologic or lymphatic dissemination of the organism. Resolution of reactivation tuberculosis leaves characteristic radiographic findings. Dense nodules in the pulmonary hila, with or without obvious calcification, upper lobe fibronodular scarring, and bronchiectasis with volume loss are common findings.

In patients with early HIV infection, the radiographic features of tuberculosis resemble those in patients without HIV infection. In contrast, atypical radiographic features predominate in patients with late-stage HIV infection. These patients often display lower lung zone, diffuse, or miliary infiltrates, pleural effusions, and involvement of hilar and, in particular, mediastinal lymph nodes.

Special Examinations

The tuberculin **skin test** identifies individuals who have been infected with *M tuberculosis* but does not distinguish between active and latent infection. The test is used to evaluate a person who has symptoms of tuberculosis, an asymptomatic person who may be infected with *M tuberculosis* (eg, after contact exposure), or to establish the prevalence of tuberculous infection in a population. Routine testing of individuals at low risk for tuberculosis is not recommended. The Mantoux test is the preferred method: 0.1 mL of purified protein derivative (PPD) containing 5 tuberculin units is injected intradermally on the volar surface of the forearm using a 27-gauge needle on a tuberculin syringe. The transverse width in millimeters of induration at the skin test site should be measured after 48–72 hours. Table 9–10 summarizes the criteria established by the Centers for Disease Control and Prevention (CDC) for interpretation of the Mantoux tuberculin skin test. Different criteria for determination of a positive reaction are used, based on the prior likelihood of infection, to maximize the performance of the test. In patients who have serial testing, a **tuberculin skin test conversion** is defined as an increase of 10 mm of induration within a 2-year period regardless of patient age.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Table 9–10. Classification of positive tuberculin skin test

reactions.[1]	
Reaction Size	**Group**
5 mm	1. HIV-positive persons. 2. Recent contacts of individuals with active tuberculosis. 3. Persons with fibrotic changes on chest x-rays suggestive of prior tuberculosis. 4. Patients with organ transplants and other immunosuppressed patients (receiving the equivalent of > 15 mg/d of prednisone for 1 month or more).
10 mm	1. Recent immigrants (< 5 years) from countries with a high prevalence of tuberculosis (eg, Asia, Africa, Latin America). 2. HIV-negative injection drug users. 3. Mycobacteriology laboratory personnel. 4. Residents of and employees[2] in the following high-risk congregate settings: correctional institutions; nursing homes and other long-term facilities for the elderly; hospitals and other health care facilities; residential facilities for AIDS

	patients; and homeless shelters. 5. Persons with the following medical conditions that increase the risk of tuberculosis: gastrectomy, 10% below ideal body weight, jejunoileal bypass, diabetes mellitus, silicosis, advanced chronic kidney disease, some hematologic disorders, (eg, leukemias, lymphomas), and other specific malignancies (eg, carcinoma of the head or neck and lung). 6. Children < 4 years of age or infants, children, and adolescents exposed to adults at high risk.
15 mm	1. Persons with no risk factors for tuberculosis.

[1] A tuberculin skin test reaction is considered positive if the transverse diameter of the *indurated* area reaches the size required for the specific group. All other reactions are considered negative.

[2] For persons who are otherwise at low risk and are tested at entry into employment, a reaction of > 15 mm induration is considered positive.

Source: Screening for tuberculosis and tuberculosis infection in high-risk populations: recommendations of the Advisory Council for the Elimination of Tuberculosis. MMWR Morb Mortal Wkly Rep. 1995 Sep 8;44(RR-11):19–34. [PMID: 7565540]

In general, it takes 2–10 weeks after tuberculosis infection for an immune response to PPD to develop. Both false-positive and false-negative results occur. False-positive tuberculin skin test reactions occur in persons previously vaccinated against *M tuberculosis* with bacillus Calmette-Guérin (BCG) (extract of *Mycobacterium bovis*) and in those infected with nontuberculous mycobacteria. False-negative tuberculin skin test reactions may result from improper testing technique, concurrent infections, malnutrition, advanced age, immunologic disorders, lymphoreticular malignancies, corticosteroid therapy, chronic kidney disease, HIV infection, and fulminant tuberculosis. Some individuals with latent tuberculosis infection may have a negative skin test reaction when tested many years after exposure.

Serial testing may create a false impression of skin test conversion. Dormant mycobacterial sensitivity is sometimes restored by the antigenic challenge of the initial skin test. This phenomenon is called "boosting." A two-step testing procedure is used to reduce the likelihood that a boosted tuberculin reaction will be misinterpreted as a recent infection. Following a negative tuberculin skin test, the person is retested in 1–3 weeks. If the second test is negative, the person is uninfected or anergic; if positive, a boosted reaction is likely. Two-step testing should be used for the initial tuberculin skin testing of individuals who will be tested repeatedly, such as health care workers. Anergy testing is not recommended for routine use to distinguish a true-negative result from anergy. Poor anergy test standardization and lack of outcome data limit the evaluation of its effectiveness. Interpretation of the tuberculin skin test in persons who have previously received BCG vaccination is the same as in those who have not had BCG.

Novel in vitro T-cell based assays promise significant change in the identification of persons with latent *M tuberculosis* infection. Potential advantages of in vitro testing include reduced variability and subjectivity associated with placing and reading the PPD, fewer false-positive results from prior BCG vaccination, and better discrimination of positive responses due to nontuberculous mycobacteria.

Persons with concomitant HIV and tuberculosis infection usually respond best when the HIV infection is treated concurrently. In some cases, prolonged antituberculous therapy may be warranted. Therefore, all patients with tuberculosis infection should be tested for HIV within 2 months after diagnosis.

Treatment

General Measures

The goals of therapy are to eliminate all tubercle bacilli from an infected individual while avoiding the emergence of clinically significant drug resistance. The basic principles of antituberculous treatment are (1) to administer multiple drugs to which the organisms are susceptible; (2) to add at least two new antituberculous agents to a regimen when treatment failure is suspected; (3) to provide the safest, most effective therapy in the shortest period of time; and (4) to ensure adherence to therapy.

All suspected and confirmed cases of tuberculosis should be reported promptly to local and state public health authorities. Public health departments will perform case investigations on sources and patient contacts to determine if other individuals with untreated, infectious tuberculosis are present in the community. They can identify infected contacts eligible for treatment of latent tuberculous infection, and ensure that a plan for monitoring adherence to therapy is established for each patient with tuberculosis. Patients with tuberculosis should be treated by physicians who are skilled in the management of this infection. Clinical expertise is especially important in cases of drug-resistant tuberculosis.

Nonadherence to antituberculous treatment is a major cause of treatment failure, continued transmission of tuberculosis, and the development of drug resistance. Adherence to treatment can be improved by providing detailed patient education about tuberculosis and its treatment in addition to a case manager who oversees all aspects of an individual patient's care. **Directly observed therapy (DOT)**, which requires that a health care worker physically observe the patient ingest antituberculous medications in the home, clinic, hospital, or elsewhere, also improves adherence to treatment. The importance of direct observation of therapy cannot be overemphasized. The CDC recommends DOT for all patients with drug-resistant tuberculosis and for those receiving intermittent (twice- or thrice-weekly) therapy.

Hospitalization for initial therapy of tuberculosis is not necessary for most patients. It should be considered if a patient is incapable of self-care or is likely to expose new, susceptible individuals to tuberculosis. Hospitalized patients with active disease require a private room with negative-pressure ventilation until tubercle bacilli are no longer found in their sputum ("smear-negative") on three consecutive smears taken on separate days.

Additional treatment considerations can be found in Chapter 33: Bacterial & Chlamydial Infections. Characteristics of antituberculous drugs are provided in Table 9–11. More complete information can be obtained from the CDC's Division of Tuberculosis Elimination Web site at http://www.cdc.gov/tb/.

Table 9–11. Characteristics of antituberculous drugs.

Drug	**Most Common Side Effects**	**Tests for Side Effects**	**Drug Interactions**	**Remarks**
Isoniazid	Peripheral neuropathy, hepatitis, rash, mild CNS effects.	AST and ALT; neurologic examination.	Phenytoin (synergistic); disulfiram.	Bactericidal to both extracellular and intracellular organisms. Pyridoxine, 10 mg orally daily as prophylaxis for neuritis; 50–100 mg orally daily as treatment.

Rifampin	Hepatitis, fever, rash, flu-like illness, gastrointestinal upset, bleeding problems, kidney failure.	CBC, platelets, AST and ALT.	Rifampin inhibits the effect of oral contraceptives, quinidine, corticosteroids, warfarin, methadone, digoxin, oral hypoglycemics; aminosalicylic acid may interfere with absorption of rifampin. Significant interactions with protease	Bactericidal to all populations of organisms. Colors urine and other body secretions orange. Discoloring of contact lenses.

			inhibitors and nonnucleoside reverse transcriptase inhibitors.	
Pyrazinamide	Hyperuricemia, hepatotoxicity, rash, gastrointestinal upset, joint aches.	Uric acid, AST, ALT.	Rare.	Bactericidal to intracellular organisms.
Ethambutol	Optic neuritis (reversible with discontinuance of drug; rare at 15 mg/kg); rash.	Red-green color discrimination and visual acuity (difficult to test in children under 3 years of age).	Rare.	Bacteriostatic to both intracellular and extracellular organisms. Mainly used to inhibit development of resistant

				mutants. Use with caution in kidney disease or when ophthalmologic testing is not feasible.
Streptomycin	Eighth nerve damage, nephrotoxicity.	Vestibular function (audiograms); BUN and creatinine.	Neuromuscular blocking agents may be potentiated and cause prolonged paralysis.	Bactericidal to extracellular organisms. Use with caution in older patients or those with kidney disease.

ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; CBC, complete blood count.

Treatment of Tuberculosis in HIV-Negative Persons

Most patients with previously untreated pulmonary tuberculosis can be effectively treated with either a 6-month or a 9-month regimen, though the 6-month regimen is preferred. The initial phase of a 6-month regimen consists of 2 months of daily isoniazid, rifampin, pyrazinamide, and ethambutol. Once the isolate is determined to be isoniazid-sensitive, ethambutol may be discontinued. If the *M tuberculosis* isolate is susceptible to isoniazid and rifampin, the second phase of therapy consists of isoniazid and rifampin for a minimum of 4 additional months, with treatment to extend at least 3 months beyond documentation of conversion of sputum cultures to negative for *M tuberculosis*. If DOT is used, medications may be given intermittently using one of three regimens: (1) Daily isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months, followed by isoniazid and rifampin two or three times each week for 4 months if susceptibility to isoniazid and rifampin is demonstrated. (2) Daily isoniazid, rifampin, pyrazinamide, and ethambutol for 2 weeks, then administration of the same agents twice weekly for 6 weeks followed by administration of isoniazid and rifampin twice each week for 4 months if susceptibility to isoniazid and rifampin is demonstrated. (3) Thrice-weekly administration of isoniazid, rifampin, pyrazinamide, and ethambutol for 6 months.

Patients who cannot or should not (eg, pregnant women) take pyrazinamide should receive daily isoniazid and rifampin along with ethambutol for 4–8 weeks. If susceptibility to isoniazid and rifampin is demonstrated or drug resistance is unlikely, ethambutol can be discontinued and isoniazid and rifampin may be given twice a week for a total of 9 months of therapy. If drug resistance is a concern, patients should receive isoniazid, rifampin, and ethambutol for 9 months. Patients with smear- and culture-negative disease (eg, pulmonary tuberculosis diagnosed on clinical grounds) and patients for whom drug susceptibility testing is not available can be treated with 6 months of isoniazid and rifampin combined with pyrazinamide for the first 2 months. This regimen assumes low prevalence of drug resistance. Previous guidelines have used streptomycin interchangeably with ethambutol. Increasing worldwide streptomycin resistance has made this drug less useful as empiric therapy.

When a twice-weekly or thrice-weekly regimen is used instead of a daily regimen, the dosages of isoniazid, pyrazinamide, and ethambutol or streptomycin must be increased. Recommended dosages for the initial treatment of tuberculosis are listed in Table 9–12. Fixed-dose combinations of isoniazid and rifampin (Rifamate) and of isoniazid, rifampin, and pyrazinamide (Rifater) are available to simplify treatment. Single tablets improve compliance but are more expensive than the individual drugs purchased separately.

Table 9–12. Recommended dosages for the initial treatment of tuberculosis.

Drugs	**Daily**	**Cost**[1]	**Twice a Week**[2]	**Cost**[1]**/wk**	**Three Times a Week**[2]	**Cost**[1]**/wk**
Isoniazid	5 mg/kg Max: 300 mg/dose	$0.21/300 mg	15 mg/kg Max: 900 mg/dose	$1.26	15 mg/kg Max: 900 mg/dose	$1.89
Rifampin	10 mg/kg Max: 600 mg/do	$5.15/600 mg	10 mg/kg Max: 600 mg/do	$10.30	10 mg/kg Max: 600 mg/do	$15.45

	se		se		se	
Pyrazinamide	15–30 mg/kg Max: 2 g/dose	$4.84/2 g	50–70 mg/kg Max: 4 g/dose	$19.36	50–70 mg/kg Max: 3 g/dose	$21.78
Ethambutol	5–25 mg/kg Max: 2.5 g/dose	$11.33/2.5 g	50 mg/kg Max: 2.5 g/dose	$22.66	25–30 mg/kg Max: 2.5 g/dose	$33.99
Streptomycin	15 mg/kg Max: 1 g/dose	$9.10/1 g	25–30 mg/kg Max: 1.5 g/dose	$36.40	25–30 mg/kg Max: 1.5 g/dose	$54.60

[2] All intermittent dosing regimens should be used with directly observed therapy.

Treatment of Tuberculosis in HIV-Positive Persons

Management of tuberculosis is rendered even more complex in patients with concomitant HIV disease. Experts in the management of both tuberculosis and HIV disease should be involved in the care of such patients. The CDC has published detailed recommendations for the treatment of tuberculosis in HIV-positive patients. These documents can be obtained by accessing the CDC Division of Tuberculosis Elimination Web site at http://www.cdc.gov/tb/.

The basic approach to HIV-positive patients with tuberculosis is similar to that detailed above for patients without HIV disease. Additional considerations in HIV-positive patients include (1) longer duration of therapy and (2) drug interactions between rifamycin derivatives such as rifampin and rifabutin, used to treat tuberculosis, and some of the protease inhibitors and nonnucleoside reverse transcriptase inhibitors (NNRTIs), used to treat HIV (see above Web site). DOT should be used for all HIV-positive tuberculosis patients. Pyridoxine (vitamin B_6), 25–50 mg orally each day, should be administered to all HIV-positive patients being treated with isoniazid to reduce central and peripheral nervous system side effects.

Treatment of Drug-Resistant Tuberculosis

Patients with drug-resistant *M tuberculosis* infection require careful supervision and management. Clinicians who are unfamiliar with the treatment of drug-resistant tuberculosis should seek expert advice. Tuberculosis resistant only to isoniazid can be successfully treated with a 6-month regimen of rifampin, pyrazinamide, and ethambutol or streptomycin or a 12-month regimen of rifampin and ethambutol. When isoniazid resistance is documented during a 9-month regimen without pyrazinamide, isoniazid should be discontinued. If ethambutol was part of the initial regimen, rifampin and ethambutol should be continued for a minimum of 12 months. If ethambutol was not part of the initial regimen, susceptibility tests should be repeated and two other drugs to which the organism is susceptible should be added. Treatment of *M tuberculosis* isolates resistant to agents other than isoniazid and treatment of drug resistance in HIV-infected patients require expert consultation.

Multidrug-resistant tuberculosis (MDRTB) calls for an individualized daily directly observed treatment plan under the supervision of a clinician experienced in the management of this entity. Treatment regimens are based on the patient's overall status and the results of susceptibility studies. Most MDRTB isolates are resistant to at least isoniazid and rifampin and require a minimum of three drugs to which the organism is susceptible. These regimens are continued until culture conversion is documented, and then a two-drug regimen is then continued for at least another 12 months. Some experts recommend at least 18–24 months of a three-drug regimen.

Treatment of Extrapulmonary Tuberculosis

In most cases, regimens that are effective for treating pulmonary tuberculosis are also effective for treating extrapulmonary disease. However, many experts recommend 9 months of therapy when miliary, meningeal, or bone and joint disease is present. Treatment of skeletal tuberculosis is enhanced by early surgical drainage and debridement of necrotic bone. Corticosteroid therapy has been shown to help prevent cardiac constriction from tuberculous pericarditis and to reduce neurologic complications from tuberculous meningitis (see Chapter 33: Bacterial & Chlamydial Infections).

Treatment of Pregnant or Lactating Women

Tuberculosis in pregnancy is usually treated with isoniazid, rifampin, and ethambutol. Ethambutol can be excluded if isoniazid resistance is unlikely. Therapy is continued for 9 months. Since the risk of teratogenicity with pyrazinamide has not been clearly defined, pyrazinamide should be used only if resistance to other drugs is documented and susceptibility to pyrazinamide is likely. Streptomycin is contraindicated in pregnancy because it may cause congenital deafness. Pregnant women taking isoniazid should receive pyridoxine (vitamin B6), 10–25 mg orally once a day, to prevent peripheral neuropathy.

Small concentrations of antituberculous drugs are present in breast milk and are not known to be harmful to nursing newborns. Therefore, breastfeeding is not contraindicated while receiving antituberculous therapy.

Treatment Monitoring

Adults should have measurements of serum bilirubin, hepatic enzymes, urea nitrogen, creatinine, and a complete blood count (including platelets) before starting chemotherapy for tuberculosis. Visual acuity and red-green color vision tests are recommended before initiation of ethambutol and serum uric acid before starting pyrazinamide. Audiometry should be performed if streptomycin therapy is initiated.

Routine monitoring of laboratory tests for evidence of drug toxicity during therapy is not recommended, unless baseline results are abnormal or liver disease is suspected. Monthly questioning for symptoms of drug toxicity is advised. Patients should be educated about common side effects of antituberculous medications and instructed to seek medical attention should these symptoms occur. Monthly follow-up of outpatients is recommended, including sputum smear and culture for *M tuberculosis* until cultures convert to negative. Patients with negative sputum cultures after 2 months of treatment should have at least one additional sputum smear and culture performed at the end of therapy. Patients with MDRTB should have sputum cultures performed monthly during the entire course of treatment. A chest radiograph at the end of therapy provides a useful baseline for any future films.

Patients whose cultures do not become negative or whose symptoms do not resolve despite 3 months of therapy should be evaluated for drug-resistant organisms and for nonadherence to the treatment regimen. DOT is required for the remainder of the treatment regimen, and the addition of at least two drugs not previously given should be considered pending repeat drug susceptibility testing. The clinician should seek expert assistance if drug resistance is newly found, if the patient remains symptomatic, or if smears or cultures remain positive.

Patients with only a clinical diagnosis of pulmonary tuberculosis (smears and cultures negative for *M tuberculosis*) whose symptoms and radiographic abnormalities are unchanged after 3 months of treatment usually either have another process or have had tuberculosis in the past.

Treatment of Latent Tuberculosis

Treatment of latent tuberculous infection is essential to controlling and eliminating tuberculosis in the United States. Treatment of latent tuberculous infection substantially reduces the risk that infection will progress to active disease. Targeted testing is used to identify persons who are at high risk for tuberculosis and who stand to benefit from treatment of latent infection. Table 9–10 defines high-risk groups and gives the tuberculin skin test criteria for treatment of latent tuberculous infection. In general, patients with a positive tuberculin skin test who are at increased risk for exposure or disease are treated. It is essential that each person who meets the criteria for treatment of latent tuberculous infection undergo a careful assessment to exclude active disease. A history of past treatment for tuberculosis and contraindications to treatment should be sought. All patients at risk for HIV infection should be tested for HIV. Patients suspected of having tuberculosis should receive one of the recommended multidrug regimens for active disease until the diagnosis is confirmed or excluded.

Some close contacts of persons with active tuberculosis should be evaluated for treatment of latent tuberculous infection despite a negative tuberculin skin test reaction (< 5 mm induration). These include immunosuppressed persons and those who may develop disease quickly after tuberculous infection. Close contacts who have a negative tuberculin skin test reaction on initial testing should be retested 10–12 weeks later.

Several treatment regimens for both HIV-negative and HIV-positive persons are available for the treatment of latent tuberculous infection: (1) **Isoniazid:** A 9-month regimen (minimum of 270 doses administered within 12 months) is considered optimal. Dosing options include a daily dose of 300 mg or twice-weekly doses of 15 mg/kg. Persons at risk for developing isoniazid-associated peripheral neuropathy (diabetes mellitus, uremia, malnutrition, alcoholism, HIV infection, pregnancy, seizure disorder) may be given supplemental pyridoxine (vitamin B_6), 10–50 mg/d. (2) **Rifampin and pyrazinamide:** A 2-month regimen (60 doses administered within 3 months) of daily rifampin (10 mg/kg up to a maximum dose of 600 mg) and pyrazinamide (15–20 mg/kg up to a maximum dose of 2 g) is recommended. (3) **Rifampin:** Patients who cannot tolerate isoniazid or pyrazinamide can be considered for a 4-month regimen (minimum of 120 doses administered within 6 months) of rifampin. HIV-positive patients receiving protease inhibitors or NNRTIs who are given rifampin require management by experts in both tuberculosis and HIV disease (see Treatment of Tuberculosis in HIV-Positive Persons, above).

Contacts of persons with isoniazid-resistant, rifampin-sensitive tuberculosis should receive a 2-month regimen of rifampin and pyrazinamide or a 4-month regimen of daily rifampin alone. Contacts of persons with MDRTB should receive two drugs to which the infecting organism has demonstrated susceptibility. Tuberculin skin test-negative and HIV-negative contacts may be observed without treatment or treated for 6 months. HIV-positive contacts should be treated for 12 months. All contacts of persons with MDRTB should have 2 years of follow up regardless of treatment.

Persons with a positive tuberculin skin test (5 mm of induration) and fibrotic lesions suggestive of old tuberculosis on chest radiographs who have no evidence of active disease and no history of treatment for tuberculosis should receive 9 months of isoniazid, or 2 months of rifampin and pyrazinamide, or 4 months of rifampin (with or without isoniazid). Pregnant or breastfeeding women with latent tuberculosis should receive either daily or twice-weekly isoniazid with pyridoxine (vitamin B6).

Baseline laboratory testing is indicated for patients at risk for liver disease, patients with HIV infection, women who are pregnant or within 3 months of delivery, and persons who use alcohol regularly. Patients receiving treatment for latent tuberculous infection should be evaluated once a month to assess for symptoms and signs of active tuberculosis and hepatitis and for adherence to their treatment regimen. Routine laboratory testing during treatment is indicated for those with abnormal baseline laboratory tests and for those at risk for developing liver disease.

Vaccine BCG is an antimycobacterial vaccine developed from an attenuated strain of *M bovis*. Millions of individuals worldwide have been vaccinated with BCG. However, it is not generally recommended in the United States because of the low prevalence of tuberculous infection, the vaccine's interference with the ability to determine latent tuberculous infection using tuberculin skin test reactivity, and its variable effectiveness against pulmonary tuberculosis. BCG vaccination in the United States should only be undertaken after consultation with local health officials and experts in the management of tuberculosis. Vaccination of health care workers should be considered on an individual basis in settings in which a high percentage of tuberculosis patients are infected with strains resistant to both isoniazid and rifampin, in which transmission of such drug-resistant *M tuberculosis* and subsequent infection are likely, and in which comprehensive tuberculous infection-control precautions have been implemented but have not been successful. The BCG vaccine is contraindicated in persons with impaired immune responses due to disease or medications.

Prognosis

Almost all properly treated patients with tuberculosis can be cured. Relapse rates are less than 5% with current regimens. The main cause of treatment failure is nonadherence to therapy.

Pulmonary Disease Caused by Nontuberculous Mycobacteria

Essentials of Diagnosis

- Chronic cough, sputum production, and fatigue; less commonly: malaise, dyspnea, fever, hemoptysis, and weight loss.
- Parenchymal infiltrates on chest radiograph, often with thin-walled cavities, that spread contiguously and often involve overlying pleura.
- Isolation of nontuberculous mycobacteria in a sputum culture.

General Considerations

Mycobacteria other than *M tuberculosis*—nontuberculous mycobacteria (NTM), sometimes referred to as "atypical" mycobacteria—are ubiquitous in water and soil and have been isolated from tap water. There appears to be a continuing increase in the number and prevalence of NTM species. Marked geographic variability exists, both in the NTM species responsible for disease and in the prevalence of disease. These organisms are not considered communicable from person to person, have distinct laboratory characteristics, and are often resistant to most antituberculous drugs. See Chapter 33: Bacterial & Chlamydial Infections for further information.

Definition & Pathogenesis

The diagnosis of lung disease caused by NTM is based on a combination of clinical, radiographic, and bacteriologic criteria and the exclusion of other diseases that can resemble the condition. Specific diagnostic criteria are discussed below. Complementary data are important for diagnosis because NTM organisms can reside in or colonize the airways without causing clinical disease, especially in patients with AIDS, and many patients have preexisting lung disease that may make their chest radiographs abnormal.

Mycobacterium avium complex (MAC) is the most frequent cause of NTM pulmonary disease in humans in the United States. *Mycobacterium kansasii* is the next most frequent pulmonary pathogen. Other NTM causes of pulmonary disease include *Mycobacterium abscessus, Mycobacterium xenopi*, and *Mycobacterium malmoense;* the list of more unusual etiologic NTM species is long. Most NTM cause a chronic pulmonary infection that resembles tuberculosis but tends to progress more slowly. Disseminated disease is rare in immunocompetent hosts; however, disseminated MAC disease is common in patients with AIDS.

Clinical Findings

Symptoms and Signs

NTM infection among immunocompetent hosts frequently presents in one of three prototypical patterns: cavitary, upper lobe lesions in older male smokers that may mimic *M tuberculosis*; nodular bronchiectasis affecting the mid lung zones in middle-aged women with chronic cough; and hypersensitivity pneumonitis following environmental exposure. Most patients with NTM infection experience a chronic cough, sputum production, and fatigue. Less common symptoms include malaise, dyspnea, fever, hemoptysis, and weight loss. Symptoms from coexisting lung disease (COPD, bronchiectasis, previous mycobacterial disease, cystic fibrosis, and pneumoconiosis) may confound the evaluation. In patients with bronchiectasis, coinfection with NTM and *Aspergillus* is a negative prognostic factor. New or worsening infiltrates as well as adenopathy or pleural effusion (or both) are described in HIV-positive patients with NTM infection as part of the immune reconstitution inflammatory syndrome following institution of highly active antiretroviral therapy.

Laboratory Findings

The diagnosis of NTM infection rests on recovery of the pathogen from cultures. Sputum cultures positive for atypical mycobacteria do not prove infection because NTM may exist as saprophytes colonizing the airways or may be environmental contaminants. Bronchial washings are considered to be more sensitive than expectorated sputum samples; however, their specificity for clinical disease is not known.

Bacteriologic criteria have been proposed based on studies of patients with cavitary disease with MAC or *M kansasii.* Diagnostic criteria in immunocompetent persons include the following: positive culture results from at least two separate expectorated sputum samples; or positive culture from at least one bronchial wash; or a positive culture from pleural fluid or any other normally sterile site. The diagnosis can also be established by demonstrating NTM cultured from a lung biopsy, bronchial wash, or sputum plus histopathologic changes such as granulomatous inflammation in a lung biopsy. Rapid species identification of some NTM is possible using DNA probes or high-pressure liquid chromatography.

Diagnostic criteria are less stringent for patients with severe immune suppression. HIV-infected patients may show significant MAC growth on culture of bronchial washings without clinical infection; therefore, HIV patients being evaluated for MAC infection must be considered individually.

In general, drug susceptibility testing on cultures of NTM is not recommended except for the following NTM: (1) *M kansasii* to rifampin; (2) rapid growers (such as *Mycobacterium fortuitum, Mycobacterium chelonae, M abscessus*) to amikacin, doxycycline, imipenem, fluoroquinolones, clarithromycin, cefoxitin, and sulfonamides.

Imaging

Chest radiographic findings include infiltrates that are progressive or persist for at least 2 months, cavitary lesions, and multiple nodular densities. The cavities are often thin-walled and have less surrounding parenchymal infiltrate than is commonly seen with MTB infections. Evidence of contiguous spread and pleural involvement is often present. High-resolution CT of the chest may show multiple small nodules with or without multifocal bronchiectasis. Progression of pulmonary infiltrates during therapy or lack of radiographic improvement over time are poor prognostic signs and also raise concerns about secondary or alternative pulmonary processes. Clearing of pulmonary infiltrates due to NTM is slow.

Treatment

Establishing NTM infection does not mandate treatment in all cases, for two reasons. First, clinical disease may never develop in some patients, particularly asymptomatic patients with few organisms isolated from single specimens. Second, the spectrum of clinical disease severity is very wide; in patients with mild or slowly progressive symptoms, traditional chemotherapeutic regimens using a combination of agents may lead to drug-induced side effects worse than the disease itself.

Specific treatment regimens and responses to therapy vary with the species of NTM. Non-HIV-infected patients with MAC pulmonary disease usually receive a combination of daily clarithromycin or azithromycin, rifampin or rifabutin, and ethambutol. Streptomycin is considered for the first 2 months as tolerated. The optimal duration of treatment is unknown, but therapy should be continued for 12 months after sputum conversion. Medical treatment is initially successful in about two-thirds of cases, but relapses after treatment are common; long-term benefit is demonstrated in about half of all patients. Those who do not respond favorably generally have active but stable disease. Surgical resection is an alternative for the patient with progressive disease that responds poorly to chemotherapy; the success rate with surgical therapy is good. Disease caused by *M kansasii* responds well to drug therapy. A daily regimen of rifampin, isoniazid, and ethambutol for at least 18 months with a minimum of 12 months of negative cultures is usually successful. Rapidly growing mycobacteria (*M abscessus*, *M fortuitum*, *M chelonae*) are generally resistant to standard antituberculous therapy.

When to Refer

Patients with rapidly growing mycobacteria infection should be referred for expert management.

mycobacteria. Chest. 2008 Jan;133(1):243–51. [PMID: 18187749]

Griffith DE et al. An official ATS/IDSA statement: diagnosis, treatment, and prevention of nontuberculous mycobacterial diseases. Am J Respir Crit Care Med. 2007 Feb 15;175(4):367–416. [PMID: 17277290]

Screening for Lung Cancer

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Periodic evaluation of asymptomatic people at high risk for lung cancer is an attractive strategy without demonstrated benefit. Available evidence from the Mayo Lung Project suggests that serial chest radiographs can identify a significant number of early stage malignancies but that neither disease-specific mortality from lung cancer nor all-cause mortality is affected by screening. The illusory benefits of screening have been attributed to lead time, length time, and overdiagnosis biases. To date, no major advisory organization recommends screening for lung cancer.

The availability of rapid-acquisition, low-dose helical computed tomography (LDCT) has rekindled enthusiasm for lung cancer screening. LDCT is a very sensitive test. Compared with chest radiography, LDCT identifies between four and ten times the number of asymptomatic lung malignancies. LDCT may also increase the number of false-positive tests, unnecessary diagnostic procedures, and overdiagnosis. A mortality benefit remains to be proved. The National Lung Cancer Screening Trial is an ongoing NCI-funded multicenter trial to determine whether using LDCT to screen current or former heavy smokers for lung cancer will improve mortality in this population. Information is available at http://www.cancer.gov/NLST/.

Screening for lung cancer with biomolecular markers remains an area of study. A variety of strategies that evaluate patterns of volatile organic compounds in exhaled breath, or DNA alterations in exhaled breath condensate have been described, although lack clinical validation.

Solitary Pulmonary Nodule

A solitary pulmonary nodule, sometimes referred to as a "coin lesion," is a < 3 cm isolated, rounded opacity on the chest imaging outlined by normal lung and not associated with infiltrate, atelectasis, or adenopathy. Most are asymptomatic and represent an unexpected finding on chest radiography or CT scanning. The finding is important because it carries a significant risk of malignancy. The frequency of malignancy in surgical series ranges from 10% to 68% depending on patient population. Most benign nodules are infectious granulomas. **Benign neoplasms** such as hamartomas account for less than 5% of solitary nodules.

The goals of evaluation are to identify and resect malignant tumors in patients who stand to benefit from resection while avoiding invasive procedures in benign disease. The task is to identify nodules with a sufficiently high probability of malignancy to warrant biopsy or resection or a sufficiently low probability of malignancy to justify observation.

Symptoms alone rarely establish the cause, but clinical and radiographic data can be used to assess the probability of malignancy. The patient's age is important. Malignant nodules are rare in persons under age 30. Above age 30, the likelihood of malignancy increases with age. Smokers are at increased risk, and the likelihood of malignancy increases with the number of cigarettes smoked daily. Patients with a prior malignancy have a higher likelihood of having a malignant solitary nodule.

The first and most important step in the radiographic evaluation is to review old radiographs. Comparison with prior studies allows estimation of doubling time, which is an important marker for malignancy. Rapid progression (doubling time less than 30 days) suggests infection; long-term stability (doubling time greater than 465 days) suggests benignity. Certain radiographic features help in estimating the probability of malignancy. Size is correlated with malignancy. A recent study of solitary nodules identified by CT scan showed a 1% malignancy rate in those measuring 2–5 mm, 24% in 6–10 mm, 33% in 11–20 mm, and 80% in 21–45 mm. The appearance of a smooth, well-defined edge is characteristic of a benign process. Ill-defined margins or a lobular appearance suggest malignancy. A high-resolution CT finding of spiculated margins and a peripheral halo are both highly associated with malignancy. Calcification and its pattern are also helpful clues. Benign lesions tend to have dense calcification in a central or laminated pattern. Malignant lesions are associated with sparser calcification that is typically stippled or eccentric. Cavitary lesions with thick (> 16 mm) walls are much more likely to be malignant. High-resolution CT offers better resolution of these characteristics than chest radiography and is more likely to detect lymphadenopathy or the presence of multiple lesions. Chest CT is indicated in any suspicious solitary pulmonary nodule.

Treatment

Based on clinical and radiologic data, the clinician should assign a specific probability of malignancy to the lesion. The decision whether and how to obtain a diagnostic biopsy depends on the interpretation of this probability in light of the patient's unique clinical situation. The probabilities in parentheses below represent guidelines only and should not be interpreted as prescriptive.

In the case of solitary pulmonary nodules, a continuous probability function may be grouped into three categories. In patients with a low probability (< 5%) of malignancy (eg, age under 30, lesions stable for more than 2 years, characteristic pattern of benign calcification), watchful waiting is appropriate. Management consists of serial imaging studies (CT scans or chest radiographs) at intervals that would identify growth that would suggest malignancy. Three-dimensional reconstruction of high-resolution CT images provides a more sensitive test for growth.

Patients with a high probability (> 60%) of malignancy should proceed directly to resection following staging, provided the surgical risk is acceptable. Biopsies rarely yield a specific benign diagnosis and are not indicated.

Optimal management of patients with an intermediate probability of malignancy (5–60%) remains controversial. The traditional approach is to obtain a diagnostic biopsy either through transthoracic needle aspiration (TTNA) or bronchoscopy. Bronchoscopy yields a diagnosis in 10–

80% of procedures depending on the size of the nodule and its location. In general, the bronchoscopic yield for nodules that are < 2 cm and peripheral is low, although complications are generally rare. Newer bronchoscopic modalities such as electromagnetic navigation and ultrathin bronchoscopy are being studied, although their impact upon diagnostic yield remains uncertain. TTNA has a higher diagnostic yield, reported to be between 50% and 97%. The yield is strongly operator-dependent, however, and is affected by the location and size of the lesion. Complications are higher than bronchoscopy, with pneumothorax occurring in up to 30% of patients, with up to one-third of these patients requiring placement of a chest tube.

Disappointing diagnostic yields and a high false-negative rate (up to 20–30% in TTNA) have prompted alternative approaches. Positron emission tomography (PET) detects increased glucose metabolism within malignant lesions with high sensitivity (85–97%) and specificity (70–85%). Many diagnostic algorithms have incorporated PET into the assessment of patients with inconclusive high-resolution CT findings. A positive PET increases the likelihood of malignancy, and a negative PET correctly excludes cancer in most cases. False-negative PET scans can occur with tumors with low metabolic activity (well-differentiated adenocarcinomas, carcinoids, and bronchioloalveolar tumors), and follow-up imaging is typically performed at discrete intervals to ensure absence of growth. PET has several drawbacks, however: resolution below 1 cm is poor, the test is expensive, and availability remains limited.

Sputum cytology is highly specific but lacks sensitivity. It is used in central lesions and in patients who are poor candidates for invasive diagnostic procedures. Researchers have attempted to improve the sensitivity of sputum cytology through the use of monoclonal antibodies to proteins that are up-regulated in pulmonary malignancies. Such tests offer promise but remain research tools at this time.

Video-assisted thoracoscopic surgery (VATS) offers a more aggressive approach to diagnosis. VATS is more invasive than bronchoscopy or TTNA but is associated with less postoperative pain, shorter hospital stays, and more rapid return to function than traditional thoracotomy. These advantages have led some centers to recommend VATS resection of all solitary pulmonary nodules with intermediate probability of malignancy. In some cases, surgeons will remove the nodule and evaluate it in the operating room with frozen section. If the nodule is malignant, they will proceed to lobectomy and lymph node sampling, either thoracoscopically or through conversion to standard thoracotomy.

All patients should be provided with an estimate of the likelihood of malignancy, and their preferences should be used to help guide diagnostic and therapeutic decisions. A strategy that recommends observation may not be preferred by a patient who desires a definitive diagnosis. Similarly, a surgical approach may not be agreeable to all patients unless the presence of cancer is definitive. Patient preferences should be elicited, and patients should be well informed regarding the specific risks and benefits associated with the recommended approach as well as the alternative strategies.

Bronchial Carcinoid Tumors

Carcinoid and bronchial gland tumors are sometimes termed "bronchial adenomas." This term should be avoided because it implies that the lesions are benign when, in fact, carcinoid tumors and bronchial gland carcinomas are low-grade malignant neoplasms.

Carcinoid tumors are about six times more common than bronchial gland carcinomas, and most of them occur as pedunculated or sessile growths in central bronchi. Men and women are equally affected. Most patients are under 60 years of age. Common symptoms of bronchial carcinoid tumors are hemoptysis, cough, focal wheezing, and recurrent pneumonia. Peripherally located bronchial carcinoid tumors are rare and present as asymptomatic solitary pulmonary nodules. Carcinoid syndrome (flushing, diarrhea, wheezing, hypotension) is rare. Fiberoptic bronchoscopy may reveal a pink or purple tumor in a central airway. These lesions have a well-vascularized stroma, and biopsy may be complicated by significant bleeding. CT scanning is helpful to localize the lesion and to follow its growth over time. Octreotide scintigraphy is also available for localization of these tumors.

Bronchial carcinoid tumors grow slowly and rarely metastasize. Complications involve bleeding and airway obstruction rather than invasion by tumor and metastases. Surgical excision of clinically symptomatic lesions is often necessary, and the prognosis is generally favorable. Most bronchial carcinoid tumors are resistant to radiation and chemotherapy.

Mediastinal Masses

Various developmental, neoplastic, infectious, traumatic, and cardiovascular disorders may cause masses that appear in the mediastinum on chest radiograph. A useful convention arbitrarily divides the mediastinum into three compartments—anterior, middle, and posterior—in order to classify mediastinal masses and assist in differential diagnosis. Specific mediastinal masses have a predilection for one or more of these compartments; most are located in the anterior or middle compartment. The differential diagnosis of an anterior mediastinal mass includes thymoma, teratoma, thyroid lesions, lymphoma, and mesenchymal tumors (lipoma, fibroma). The differential diagnosis of a middle mediastinal mass includes lymphadenopathy, pulmonary artery enlargement, aneurysm of the aorta or innominate artery, developmental cyst (bronchogenic, enteric, pleuropericardial), dilated azygous or hemiazygous vein, and foramen of Morgagni hernia. The differential diagnosis of a posterior mediastinal mass includes hiatus hernia, neurogenic tumor, meningocele, esophageal tumor, foramen of Bochdalek hernia, thoracic spine disease, and extramedullary hematopoiesis. The neurogenic tumor group includes neurilemmoma, neurofibroma, neurosarcoma, ganglioneuroma, and pheochromocytoma.

Symptoms and signs of mediastinal masses are nonspecific and are usually caused by the effects of the mass on surrounding structures. Insidious onset of retrosternal chest pain, dysphagia, or dyspnea is often an important clue to the presence of a mediastinal mass. In about half of cases, symptoms are absent, and the mass is detected on routine chest radiograph. Physical findings vary depending on the nature and location of the mass.

CT scanning is helpful in management; additional radiographic studies of benefit include barium swallow if esophageal disease is suspected, Doppler sonography or venography of brachiocephalic veins and the superior vena cava, and angiography. MRI is useful; its advantages include better delineation of hilar structures and distinction between vessels and masses. MRI also allows imaging in multiple planes, whereas CT permits only axial imaging. Tissue diagnosis is necessary if a neoplastic disorder is suspected. Treatment and prognosis depend on the underlying cause of the mediastinal mass.

Interstitial Lung Disease: Introduction

Interstitial lung disease, or diffuse parenchymal lung disease, comprises a heterogeneous group of disorders that share common presentations (dyspnea), physical findings (late inspiratory crackles), and chest radiographs (septal thickening and reticulonodular changes).

The term "interstitial" is misleading since the pathologic process usually begins with injury to the alveolar epithelial or capillary endothelial cells. Persistent alveolitis may lead to obliteration of alveolar capillaries and reorganization of the lung parenchyma, accompanied by irreversible fibrosis. The process does not affect the airways proximal to the respiratory bronchioles. At least 180 disease entities may present as interstitial lung disease. Table 9–13 outlines a selected list of differential diagnoses of interstitial lung disease. In most patients, no specific cause can be identified. In the remainder, drugs and a variety of organic and inorganic dusts are the principal causes. The history—particularly the occupational and medication history—may provide evidence of a specific cause.

Table 9–13. Differential diagnosis of interstitial lung disease.
Drug-related
Antiarrhythmic agents (amiodarone)
Antibacterial agents (nitrofurantoin, sulfonamides)
Antineoplastic agents (bleomycin, cyclophosphamide, methotrexate, nitrosoureas)
Antirheumatic agents (gold salts, penicillamine)
Phenytoin
Environmental and occupational (inhalation exposures)
Dust, inorganic (asbestos, silica, hard metals, beryllium)
Dust, organic (thermophilic actinomycetes, avian antigens, *Aspergillus* species)
Gases, fumes, and vapors (chlorine, isocyanates, paraquat, sulfur dioxide)
Ionizing radiation

Talc (injection drug users)
Infections
Fungus, disseminated (*Coccidioides immitis*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*)
Mycobacteria, disseminated
Pneumocystis jiroveci
Viruses
Primary pulmonary disorders
Cryptogenic organizing pneumonitis (COP)
Idiopathic fibrosing interstitial pneumonia: Acute interstitial pneumonitis, desquamative interstitial pneumonitis, nonspecific interstitial pneumonitis, usual interstitial pneumonitis, respiratory bronchiolitis-associated interstitial lung disease
Pulmonary alveolar proteinosis
Systemic disorders
Acute respiratory distress syndrome
Amyloidosis
Ankylosing spondylitis
Autoimmune disease: Dermatomyositis, polymyositis, rheumatoid arthritis, systemic sclerosis (scleroderma), systemic lupus erythematosus
Chronic eosinophilic pneumonia
Goodpasture syndrome

Idiopathic pulmonary hemosiderosis
Inflammatory bowel disease
Langerhans cell histiocytosis (eosinophilic granuloma)
Lymphangitic spread of cancer (lymphangitic carcinomatosis)
Lymphangioleiomyomatosis
Pulmonary edema
Pulmonary venous hypertension, chronic
Sarcoidosis
Wegener granulomatosis

The connective tissue diseases are a group of immunologically mediated inflammatory disorders including rheumatoid arthritis, systemic lupus erythematosus, scleroderma, polymyositis-dermatomyositis, Sjögren syndrome, and other overlap conditions. The presence of diffuse parenchymal lung disease in the setting of an established connective tissue disease is suggestive of the etiology. In some cases, lung disease precedes the more typical manifestations of the underlying connective tissue disease by months or years.

Clinical Findings

Symptoms and Signs

The clinical consequence of widespread lung fibrosis is diminished lung compliance, which presents as restrictive lung disease. Patients usually describe an insidious onset of exertional dyspnea and cough. Sputum production is minimal. Chest examination reveals fine, late inspiratory crackles at the lung bases in 60–90% of patients. Digital clubbing is seen in 25–50% of patients at diagnosis (see Plate 47); (see photograph).

Laboratory Findings

Serologic tests for antinuclear antibodies and rheumatoid factor are positive in 20–40% of patients but are rarely diagnostic. Antineutrophil cytoplasmic antibodies (ANCAs) may be diagnostic in some clinical settings. Pulmonary function testing shows a loss of lung volume with normal to increased airflow rates (see illustration). The DL_{CO} is decreased, and hypoxemia with exercise is common. In advanced cases, pulmonary hypertension and resting hypoxemia may be present.

Imaging

The chest radiograph is normal on presentation in up to 10% of patients. More typically, it shows patchy distribution of ground-glass, reticular, or reticulonodular infiltratess. In advanced disease there are multiple small, thick-walled cystic spaces in the lung periphery ("honeycomb" lung). Honeycombing indicates the presence of locally advanced fibrosis with destruction of normal lung architecture. Conventional CT and high-resolution CT imaging reveal in greater detail the findings described on chest radiograph. In some cases, high-resolution CT may be strongly suggestive of a specific pathologic process.

Other Studies

Three diagnostic techniques are in common use: bronchoalveolar lavage, transbronchial biopsy, and surgical lung biopsy, either through an open procedure or using VATS.

Bronchoalveolar lavage may provide a specific diagnosis in cases of infection, particularly with *P jiroveci* or mycobacteria, or when cytologic examination reveals the presence of malignant cells. The findings may be suggestive and sometimes diagnostic of eosinophilic pneumonia, Langerhans cell histiocytosis, and alveolar proteinosis. Analysis of the cellular constituents of lavage fluid may suggest a specific disease, but these findings are not diagnostic.

Transbronchial biopsy through the flexible bronchoscope is easily performed in most patients. The risks of pneumothorax (5%) and hemorrhage (1–10%) are low. However, the tissue specimens recovered are small, sampling error is common, and crush artifact may complicate diagnosis. Transbronchial biopsy can make a definitive diagnosis of sarcoidosis, lymphangitic spread of carcinoma, pulmonary alveolar proteinosis, miliary tuberculosis, and Langerhans cell histiocytosis. Transbronchial biopsy cannot establish a specific diagnosis of idiopathic interstitial pneumonia. These patients generally require surgical lung biopsy.

Surgical lung biopsy is the standard for diagnosis of interstitial lung disease. Two or three biopsies taken from multiple sites in the same lung, including apparently normal tissue, may yield a specific diagnosis as well as prognostic information regarding the extent of fibrosis versus active inflammation. Patients under age 60 without a specific diagnosis generally should undergo surgical lung biopsy. In older and sicker patients, the risks and benefits must be weighed carefully for three reasons: (1) the morbidity of the procedure can be significant; (2) a definitive diagnosis may not be possible even with surgical lung biopsy; and (3) when a specific diagnosis is made, there may be no effective treatment. Empiric therapy or no treatment may be preferable to surgical lung biopsy in some patients.

Known causes of interstitial lung disease are dealt with in their specific sections. The important idiopathic forms are discussed in Idiopathic Fibrosing Interstitial Pneumonia (Formerly: Idiopathic Pulmonary Fibrosis).

Idiopathic Fibrosing Interstitial Pneumonia (Formerly:

Idiopathic Pulmonary Fibrosis)

The most common diagnosis among patients with interstitial lung disease is idiopathic fibrosing interstitial pneumonia, formerly known in the United States as "idiopathic pulmonary fibrosis" (known in the United Kingdom as "cryptogenic fibrosing alveolitis"). Historically, this diagnosis was based on clinical and radiographic criteria with only a small number of patients undergoing surgical lung biopsy. When biopsies were obtained, the common element of fibrosis led to the grouping together of several histologic patterns under the category of "idiopathic pulmonary fibrosis." These distinct histopathologic features are now recognized as being associated with different natural histories and responses to therapy (see Table 9–14). Therefore, in the evaluation of patients with idiopathic interstitial lung disease, clinicians should attempt to identify specific disorders and reserve the terms "idiopathic fibrosing interstitial pneumonia," or "cryptogenic fibrosing alveolitis" to denote only the histologic pattern of usual interstitial pneumonitis (UIP).

Table 9–14. Idiopathic fibrosing interstitial pneumonias.

Name and Clinical Presentation	Histopathology	Radiographic Pattern	Response to Therapy and Prognosis
Usual interstitial pneumonia (UIP) Age 55–60, slight male predominance. Insidious dry cough and dyspnea lasting months to years. Clubbing present at diagnosis in 25–50%. Diffuse fine late inspiratory crackles on lung auscultation. Restrictive	Patchy, temporally and geographically nonuniform distribution of fibrosis, honeycomb change, and normal lung. Type I pneumocytes are lost, and there is proliferation of alveolar type II cells. "Fibroblast foci" of actively proliferating fibroblasts and	Diminished lung volume. Increased linear or reticular bibasilar and subpleural opacities. Unilateral disease is rare. High-resolution CT scanning shows minimal ground-glass and variable honeycomb change. Areas of normal lung may be adjacent to areas of	No randomized study has demonstrated improved survival compared with untreated patients. Inexorably progressive. Response to corticosteroids and cytotoxic agents at best 15%, and these probably represent misclassification of histopatholog

ventilatory defect and reduced diffusing capacity on pulmonary function tests. ANA and RF positive in ~25% in the absence of documented collagen-vascular disease.	myofibroblasts. Inflammation is generally mild and consists of small lymphocytes. Intra-alveolar macrophage accumulation is present but is not a prominent feature.	advanced fibrosis. Between 2% and 10% have normal chest radiographs and high-resolution CT scans on diagnosis.	y. Median survival approximately 3 years, depending on stage at presentation. Current interest in antifibrotic agents.
Respiratory bronchiolitis - associated interstitial lung disease (RB-ILD)[1] Age 40–45. Presentation similar to that of UIP though in	Increased numbers of macrophages evenly dispersed within the alveolar spaces. Rare fibroblast foci, little fibrosis,	May be indistinguishable from UIP. More often presents with a nodular or reticulonodular pattern. Honeycombing rare. High-resolution CT	Spontaneous remission occurs in up to 20% of patients, so natural history unclear. Smoking cessation is essential.

younger patients. Similar results on pulmonary function tests, but less severe abnormalities. Patients with respiratory bronchiolitis are invariably heavy smokers.	minimal honeycomb change. In RB-ILD the accumulation of macrophages is localized within the peribronchiolar air spaces; in DIP,[1] it is diffuse. Alveolar architecture is preserved.	more likely to reveal diffuse ground-glass opacities and upper lobe emphysema.	Prognosis clearly better than that of UIP: median survival greater than 10 years. Corticosteroids thought to be effective, but there are no randomized clinical trials to support this view.
Acute interstitial pneumonitis (AIP) Clinically known as Hamman-Rich syndrome. Wide age	Pathologic changes reflect acute response to injury within days to weeks. Resembles organizing phase of	Diffuse bilateral airspace consolidation with areas of ground-glass attenuation on high-resolution CT scan.	Supportive care (mechanical ventilation) critical but effect of specific therapies unclear. High initial

range, many young patients. Acute onset of dyspnea followed by rapid development of respiratory failure. Half of patients report a viral syndrome preceding lung disease. Clinical course indistinguishable from that of idiopathic ARDS.	diffuse alveolar damage. Fibrosis and minimal collagen deposition. May appear similar to UIP but more homogeneous and there is no honeycomb change—though this may appear if the process persists for more than a month in a patient on mechanical ventilation.		mortality: Fifty to 90 percent die within 2 months after diagnosis. Not progressive if patient survives. Lung function may return to normal or may be permanently impaired.
Nonspecific interstitial	Nonspecific in that	May be indistinguisha	Treatment thought to be

pneumonitis (NSIP)	histopathology does not fit into better-established categories. Varying degrees of inflammation and fibrosis, patchy in distribution but uniform in time, suggesting response to single injury. Most have lymphocytic and plasma cell inflammation without fibrosis. Honeycombing present	ble from UIP. Most typical picture is bilateral areas of ground-glass attenuation and fibrosis on high-resolution CT. Honeycombing is rare.	effective, but no prospective clinical studies have been published. Prognosis overall good but depends on the extent of fibrosis at diagnosis. Median survival greater than 10 years.
Age 45–55. Slight female predominance. Similar to UIP but onset of cough and dyspnea over months, not years.			

	but scant. Some have advocated division into cellular and fibrotic subtypes.		
Cryptogenic organizing pneumonitis (COP, formerly bronchiolitis obliterans organizing pneumonia [BOOP]) Typically age 50–60 but wide variation. Abrupt onset, frequently weeks to a few months following a flu-like	Included in the idiopathic interstitial pneumonias on clinical grounds. Buds of loose connective tissue (Masson bodies) and inflammatory cells fill alveoli and distal bronchioles.	Lung volumes normal. Chest radiograph typically shows interstitial and parenchymal disease with discrete, peripheral alveolar and ground-glass infiltrates. Nodular opacities common. high-resolution CT	Rapid response to corticosteroids in two-thirds of patients. Long-term prognosis generally good for those who respond. Relapses are common.

illness. Dyspnea and dry cough prominent, but constitutional symptoms are common: fatigue, fever, and weight loss. Pulmonary function tests usually show restriction, but up to 25% show concomitant obstruction.		shows subpleural consolidation and bronchial wall thickening and dilation.	

[1] Includes desquamative interstitial pneumonia (DIP).

ANA, antinuclear antibody; ARDS, acute respiratory distress syndrome; RF, rheumatoid factor; UIP, usual interstitial pneumonia.

Patients with idiopathic fibrosing interstitial pneumonia may have any of the histologic patterns described in Table

9–14. The first step in evaluation is to identify patients whose disease is truly idiopathic. As indicated in Table 9–13, most identifiable causes of interstitial lung disease are infectious, drug-related, or environmental or occupational agents. Interstitial lung diseases associated with other medical conditions (pulmonary-renal syndromes, collagen-vascular disease) may be identified through a careful medical history. Apart from acute interstitial pneumonia, the clinical presentations of the idiopathic interstitial pneumonias are sufficiently similar to preclude a specific diagnosis. Chest radiographs and high-resolution CT scans are occasionally diagnostic. Ultimately, many patients with apparently idiopathic disease require surgical lung biopsy to make a definitive diagnosis. The importance of accurate diagnosis is twofold. First, it allows the clinician to provide accurate information about the cause and natural history of the illness. Second, accurate diagnosis helps distinguish patients most likely to benefit from therapy. Surgical lung biopsy may spare patients with UIP treatment with potentially morbid therapies.

The diagnosis of UIP can be made on clinical grounds alone in selected patients. A diagnosis of UIP can be made with 90% confidence in patients over 65 years of age who have (1) idiopathic disease by history and who demonstrate inspiratory crackles on physical examination

; (2) restrictive physiology on pulmonary function testing; (3) characteristic radiographic evidence of progressive fibrosis over several years; and (4) diffuse, patchy fibrosis with pleural-based honeycombing on high-resolution CT scan. Such patients do not need surgical lung biopsy. Note that the diagnosis of UIP cannot be confirmed on transbronchial lung biopsy since the histologic diagnosis requires a pattern of changes rather than a single pathognomonic finding. Transbronchial biopsy may exclude UIP by confirming a specific alternative diagnosis.

Audio
Recording of a person with pulmonary fibrosis. Note the fine quality of the rales and the timing at the end of inspiration. (Reproduced, with permission, from Raymond L.H. Murphy, Jr., MD: *A Simplified Introduction to Lung Sounds* [audio tape], 1977.)

Treatment of idiopathic fibrosing interstitial pneumonia is controversial. No randomized study has demonstrated that any treatment improves survival or quality of life compared with no treatment. Clinical experience suggests that patients with DIP or RB-ILD, nonspecific interstitial pneumonia (NSIP), or COP (see Table 9–14) frequently respond to corticosteroids and should be given a trial of therapy—typically prednisone, 1–2 mg/kg/d for a minimum of 2 months. The same therapy is almost uniformly ineffective in patients with UIP. Since this therapy carries significant morbidity, experts do not recommend routine use of corticosteroids in patients with UIP. There are a number of ongoing clinical trials of antifibrotic therapies, such as pirfenidone and interferon gamma-1b, as well as smaller investigations of sildenafil, thalidomide, and biologic modifiers.

Sarcoidosis

Essentials of Diagnosis

- Symptoms related to the lung, skin, eyes, peripheral nerves, liver, kidney, heart, and other tissues.
- Demonstration of noncaseating granulomas in a biopsy specimen.
- Exclusion of other granulomatous disorders.

General Considerations

Sarcoidosis is a systemic disease of unknown etiology characterized in about 90% of patients by granulomatous inflammation of the lung. The incidence is highest in North American blacks and northern European whites; among blacks, women are more frequently affected than men. Onset of disease is usually in the third or fourth decade.

Clinical Findings

Symptoms and Signs

Patients may present with malaise, fever, and dyspnea of insidious onset. Symptoms referable to the skin, eyes, peripheral nerves, liver, kidney, or heart may also cause the patient to seek care (Plate 67). Some individuals are asymptomatic and come to medical attention after abnormal findings (typically bilateral hilar and right paratracheal lymphadenopathy) on chest radiographs. Physical findings are atypical of interstitial lung disease in that crackles are uncommon on chest examination. Other findings may include erythema nodosum (see photograph), parotid gland enlargement, hepatosplenomegaly, and lymphadenopathy.

Fig.

Erythema nodosum. Nodules on the legs are usually very tender. (Reproduced, with permission, from Orkin M, Maibach HI, Dahl MV [editors]: *Dermatology*. Originally published by Appleton & Lange. Copyright © 1991 by The McGraw-Hill Companies, Inc.)

Laboratory Findings

Laboratory tests may show leukopenia, an elevated erythrocyte sedimentation rate, and hypercalcemia (about 5% of patients) or hypercalciuria (20%). Angiotensin-converting enzyme (ACE) levels are elevated in 40–80% of patients with active disease. This finding is neither sensitive nor specific enough to have diagnostic significance. Physiologic testing may reveal evidence of airflow obstruction, but restrictive changes with decreased lung volumes and diffusing capacity are more common. Skin test anergy is present in 70%. ECG may show conduction disturbances and dysrhythmias.

Imaging

Radiographic findings are variable and include bilateral hilar adenopathy alone (radiographic stage I), hilar adenopathy and parenchymal involvement (radiographic stage II), or parenchymal involvement alone (radiographic stage III). Parenchymal involvement is usually manifested radiographically by diffuse reticular infiltrates (see x-ray), but focal infiltrates, acinar shadows, nodules, and, rarely, cavitation may be seen. Pleural effusion is noted in fewer than 10% of patients.

Fig.

Pulmonary sarcoidosis. Linear streaks radiate from the central zones all the way to the periphery of the lung in all regions. This is the pattern of a diffuse interstitial pulmonary process, one of whose causes is sarcoidosis. (Courtesy of H Goldberg.)

Special Examinations

The diagnosis of sarcoidosis generally requires histologic demonstration of noncaseating granulomas in biopsies from a patient with other typical associated manifestations. Other granulomatous diseases (eg, berylliosis, tuberculosis, fungal infections) and lymphoma must be excluded. Biopsy of easily accessible sites (eg, palpable lymph nodes, skin lesions, or salivary glands) is likely to be positive. Transbronchial lung biopsy has a high yield (75–90%) as well, especially in patients with radiographic evidence of parenchymal involvement. Some clinicians believe that tissue biopsy is not necessary when stage I radiographic findings are detected in a clinical situation that strongly favors the diagnosis of sarcoidosis (eg, a young black woman with erythema nodosum). Biopsy is essential whenever clinical and radiographic findings suggest the possibility of an alternative diagnosis such as lymphoma. Bronchoalveolar lavage fluid in sarcoidosis is usually characterized by an increase in lymphocytes and a high CD4/CD8 cell ratio. Bronchoalveolar lavage does not establish a diagnosis but may be useful in following the activity of sarcoidosis in selected patients. All patients require a complete ophthalmologic evaluation.

Treatment

Indications for treatment with oral corticosteroids (prednisone, 0.5–1.0 mg/kg/d) include disabling constitutional symptoms, hypercalcemia, iritis, uveitis, arthritis, central nervous system involvement, cardiac involvement, granulomatous hepatitis, cutaneous lesions other than erythema nodosum, and progressive pulmonary lesions. Long-term therapy is usually required over months to years. Serum ACE levels usually fall with clinical improvement. Immunosuppressive drugs and cyclosporine have been tried, primarily when corticosteroid therapy has been exhausted, but experience with these drugs is limited. Anti-tumor necrosis factor (TNF) therapy with infliximab has shown some promise in extra-pulmonary sarcoidosis.

Prognosis

The outlook is best for patients with hilar adenopathy alone; radiographic involvement of the lung parenchyma is associated with a worse prognosis. Erythema nodosum portends a good outcome. About 20% of patients with lung involvement suffer irreversible lung impairment, characterized by progressive fibrosis, bronchiectasis, and cavitation. Pneumothorax, hemoptysis, mycetoma formation in lung cavities, and respiratory failure often complicate this advanced stage. Myocardial sarcoidosis occurs in about 5% of patients, sometimes leading to restrictive cardiomyopathy, cardiac dysrhythmias, and conduction disturbances. Death from pulmonary insufficiency occurs in about 5% of patients.

Patients require long-term follow-up; at a minimum, yearly physical examination, pulmonary function tests, chemistry panel, ophthalmologic evaluation, chest radiograph, and ECG.

Pulmonary Alveolar Proteinosis

Pulmonary alveolar proteinosis is a rare disease in which phospholipids accumulate within alveolar spaces. The condition may be primary (idiopathic) or secondary (occurring in immune deficiency; hematologic malignancies; inhalation of mineral dusts; or following lung infections, including tuberculosis and viral infections). Progressive dyspnea is the usual presenting symptom, and chest radiograph shows bilateral alveolar infiltrates suggestive of pulmonary edema (see x-ray, CT scan). The diagnosis is based on demonstration of characteristic findings on bronchoalveolar lavage (milky appearance and PAS-positive lipoproteinaceous material) in association with typical clinical and radiographic features. In some cases, transbronchial or surgical lung biopsy (revealing amorphous intra-alveolar phospholipid) is necessary.

Fig.

A: Pulmonary alveolar proteinosis (chest radiograph). An ill-defined right perihilar opacity is noted, extending from the hilum to the periphery of the lung. This is typical of pulmonary alveolar proteinosis, though the process is often bilateral and may be more basilar. ***B:*** Pulmonary alveolar proteinosis (CT scan). The patient is lying prone. The right and left lungs are replaced by opaque material with multiple small linear and circular lucencies. This pattern of diffuse alveolar infiltration is typical of pulmonary alveolar proteinosis. (Courtesy of H Goldberg.)

The course of the disease varies. Some patients experience spontaneous remission; others develop progressive respiratory insufficiency. Pulmonary infection with nocardia (see micrograph) or fungi may occur. Therapy for alveolar proteinosis consists of periodic whole lung lavage.

Eosinophilic Pulmonary Syndromes

Eosinophilic pulmonary syndromes are a diverse group of disorders typically characterized by eosinophilic pulmonary infiltrates, dyspnea, and cough. Many patients have constitutional symptoms, including fever. Common causes include exposure to medications (nitrofurantoin, phenytoin, ampicillin, acetaminophen, ranitidine) or infection with helminths (eg, *Ascaris*, hookworms, *Strongyloides*) or filariae (eg, *Wuchereria bancrofti, Brugia malayi*, tropical pulmonary eosinophilia). **Löffler syndrome** refers to acute eosinophilic pulmonary infiltrates in response to transpulmonary passage of helminth larvae. Pulmonary eosinophilia can also be a feature of other illnesses, including ABPA, Churg-Strauss syndrome, systemic hypereosinophilic syndromes, eosinophilic granuloma of the lung (properly referred to as pulmonary Langerhans cell histiocytosis), neoplasms, and numerous interstitial lung diseases (see x-ray). If an extrinsic cause is identified, therapy consists of removal of the offending drug or treatment of the underlying parasitic infection.

Fig.

A: Eosinophilic pneumonitis. This patient with parasite-induced eosinophilic pneumonitis has ill-defined nodular and fluffy, patchy densities scattered throughout both lungs. ***B:*** The lateral film from the same patient shows a better-defined infiltrate at the left lung base. (Courtesy of H Goldberg.)

One-third of cases are idiopathic, and there are two common syndromes. **Chronic eosinophilic pneumonia** is seen predominantly in women and is characterized by fever, night sweats, weight loss, and dyspnea. Asthma is present in half of cases. Chest radiographs often show peripheral infiltrates (see x-ray), the "photographic negative" of pulmonary edema. Bronchoalveolar lavage typically has a marked eosinophilia; peripheral blood eosinophilia is present in greater than 80%. Therapy with oral prednisone (1 mg/kg/d for 1–2 weeks followed by a gradual taper over many months) usually results in dramatic improvement; however, most patients require at least 10–15 mg of prednisone every other day for a year or more (sometimes indefinitely) to prevent relapses. **Acute eosinophilic pneumonia** is an acute, febrile illness characterized by cough and dyspnea, sometimes rapidly progressing to respiratory failure. The chest radiograph is abnormal but nonspecific. Bronchoalveolar lavage frequently shows eosinophilia but peripheral blood eosinophilia is rare at the onset of symptoms. The response to corticosteroids is usually dramatic.

Fig.

Eosinophilic pneumonia. The pulmonary infiltrate in this case is confined to the lingular portion of the left lung and extends into the upper lobe. There is also a small pleural effusion. This is one of the manifestations of eosinophilic pneumonia. (Courtesy of H Goldberg.)

Pulmonary Venous Thromboembolism

Essentials of Diagnosis

- Predisposition to venous thrombosis, usually of the lower extremities.
- One or more of the following: dyspnea, chest pain, hemoptysis, syncope.
- Tachypnea and a widened alveolar-arterial Po_2 difference.
- Characteristic defects on ventilation-perfusion lung scan, helical CT scan of the chest, or pulmonary angiogram.

General Considerations

Pulmonary venous thromboembolism, often referred to as pulmonary embolism (PE), is a common, serious, and potentially fatal complication of thrombus formation within the deep venous circulation. PE is estimated to cause 200,000 deaths each year in the United States and is the third leading cause of death among hospitalized patients. Despite this prevalence, most cases are not recognized antemortem, and less than 10% of patients with fatal emboli have received specific treatment for the condition. Management demands a vigilant systematic approach to diagnosis and an understanding of risk factors so that appropriate preventive therapy can be given.

Many substances can embolize to the pulmonary circulation, including air (during neurosurgery, from central venous catheters), amniotic fluid (during active labor), fat (long bone fractures), foreign bodies (talc in injection drug users), parasite eggs (schistosomiasis), septic emboli (acute infectious endocarditis), and tumor cells (renal cell carcinoma). The most common embolus is thrombus, which may arise anywhere in the venous circulation or heart but most often originates in the deep veins of the lower extremities. Thrombi confined to the calf rarely embolize to the pulmonary circulation. However, about 20% of calf vein thrombi propagate proximally to the popliteal and ileofemoral veins, at which point they may break off and embolize to the pulmonary circulation. Pulmonary emboli will develop in 50–60% of patients with proximal deep venous thrombosis (DVT); half of these embolic events will be asymptomatic. Approximately 50–70% of patients who have symptomatic pulmonary emboli will have lower extremity DVT when evaluated.

PE and DVT are two manifestations of the same disease. The risk factors for PE are the risk factors for thrombus formation within the venous circulation: venous stasis, injury to the vessel wall, and hypercoagulability (Virchow triad). Venous stasis increases with immobility (bed rest—especially postoperative—obesity, stroke), hyperviscosity (polycythemia), and increased central venous pressures (low cardiac output states, pregnancy). Vessels may be damaged by prior episodes of thrombosis, orthopedic surgery, or trauma. Hypercoagulability can be caused by medications (oral contraceptives, hormonal replacement therapy) or disease (malignancy, surgery) or may be the result of inherited gene defects. The most common inherited cause in white populations is resistance to activated protein C, also known as factor V Leiden. The trait is present in approximately 3% of healthy American men and in 20–40% of patients with idiopathic venous thrombosis. Other major risks for hypercoagulability include the following: deficiencies or dysfunction of protein C, protein S, and antithrombin III; prothrombin gene mutation; and the presence of antiphospholipid antibodies (lupus anticoagulant and anticardiolipin antibody).

PE has multiple physiologic effects. Physical obstruction of the vascular bed and vasoconstriction from neurohumoral reflexes both increase pulmonary vascular resistance. Massive thrombus may cause right ventricular failure. Vascular obstruction increases physiologic dead space (wasted ventilation) and leads to hypoxemia through right-to-left shunting, decreased cardiac output, and surfactant depletion causing atelectasis. Reflex bronchoconstriction promotes wheezing and increased work of breathing.

Clinical Findings

Symptoms and Signs

The clinical diagnosis of PE is notoriously difficult for two reasons. First, the clinical findings depend on both the size of the embolus and the patient's preexisting cardiopulmonary status. Second, common symptoms and signs of pulmonary emboli are not specific to this disorder (Table 9–15).

Table 9–15. Frequency of specific symptoms and signs in patients at risk for pulmonary thromboembolism.

	UPET[1] PE+ (n = 327)	**PIOPED[2] PE+ (n = 117)**	**PIOPED[2] PE– (n = 248)**
Symptoms			
Dyspnea	84%	73%	72%
Respirophasic chest pain	74%	66%	59%
Cough	53%	37%	36%
Leg pain	nr	26%	24%
Hemoptysis	30%	13%	8%
Palpitations	nr	10%	18%
Wheezing	nr	9%	11%
Anginal pain	14%	4%	6%
Signs			

Respiratory rate 16 UPET, 20 PIOPED	92%	70%	68%
Crackles (rales)	58%	51%	40%[3]
Heart rate 100/min	44%	30%	24%
Fourth heart sound (S_4)	nr	24%	13%[3]
Accentuated pulmonary component of second heart sound (S_2P)	53%	23%	13%[3]
T 37.5 °C UPET, 38.5 °C PIOPED	43%	7%	12%
Homans' sign	nr	4%	2%
Pleural friction rub	nr	3%	2%
Third heart sound (S_3)	nr	3%	4%
Cyanosis	19%	1%	2%

[1] Data from the Urokinase-Streptokinase Pulmonary Embolism Trial, as reported in Bell WR et al. The clinical features of submassive and massive pulmonary emboli. Am J Med. 1977 Mar;62(3):355–60. [PMID: 842555]

[2] Data from patients enrolled in the PIOPED I study, as reported in Stein PD et al. Clinical, laboratory, roentgenographic, and electrocardiographic findings in patients with acute pulmonary embolism and no preexisting cardiac or pulmonary disease. Chest. 1991 Sep;100(3):598–603. [PMID: 1909617]

[3] $P < .05$ comparing patients in the PIOPED I study.

PE+, confirmed diagnosis of pulmonary embolism; PE–, diagnosis of pulmonary embolism ruled out; nr, not reported.

Indeed, no single symptom or sign or combination of clinical findings is specific to PE. Some findings are fairly sensitive: dyspnea and pain on inspiration occur in 75–85% and 65–75% of patients, respectively. Tachypnea is the only sign reliably found in more than half of patients. A common clinical strategy is to use combinations of clinical findings to identify patient's risk for PE. For example, 97% of patients in the original Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED I) study with angiographically proved pulmonary emboli had one or more of three findings:

dyspnea, chest pain with breathing, or tachypnea. Wells and colleagues have published and validated a simple clinical decision rule that quantifies and dichotomizes this clinical risk assessment, allowing diversion of patients deemed unlikely to have PE to a simpler diagnostic algorithm (see Integrated Approach to Diagnosis of Pulmonary Embolism).

Laboratory Findings

The **ECG** is abnormal in 70% of patients with PE. However, the most common abnormalities are sinus tachycardia and nonspecific ST and T wave changes, each seen in approximately 40% of patients. Five percent or less of patients in the PIOPED I study had P pulmonale, right ventricular hypertrophy, right axis deviation, and right bundle branch block.

Arterial blood gases usually reveal acute respiratory alkalosis due to hyperventilation. The arterial PO_2 and the alveolar-arterial oxygen difference ($A–a–DO_2$) are usually abnormal in patients with PE compared with healthy, age-matched controls. However, arterial blood gases are not diagnostic: among patients who were evaluated in the PIOPED I study, neither the PO_2 nor the $A–a–DO_2$ differentiated between those with and those without pulmonary emboli. Profound hypoxia with a normal chest radiograph in the absence of preexisting lung disease is highly suspicious for PE.

Plasma levels of **D-dimer** , a degradation product of cross-linked fibrin, are elevated in the presence of thrombus. Using a D-dimer threshold between 300 and 500 ng/mL, a rapid quantitative enzyme-linked immunosorbent assay (ELISA) has shown a sensitivity for venous thromboembolism of 95–97% and a specificity of 45%. Therefore, a D-dimer < 500 ng/mL using the rapid ELISA provides strong evidence against venous thromboembolism, with a likelihood ratio of 0.11–0.13. Appropriate diagnostic thresholds have not been established for patients in whom D-dimer is elevated.

Serum troponin I, troponin T, and plasma beta-natriuretic peptide (BNP) levels are typically higher in patients with PE compared with those without embolism; the presence and magnitude of the elevation are not useful in diagnosis, but correlate with adverse outcomes, including death, mechanical ventilation and prolonged hospitalization.

Imaging and Special Examinations

Chest radiography

The chest radiograph is necessary to exclude other common lung diseases and to permit interpretation of the ventilation-perfusion (/) scan, but it does not establish the diagnosis by itself. The chest radiograph was normal in only 12% of patients with confirmed PE in the PIOPED I study. The most frequent findings were atelectasis, parenchymal infiltrates, and pleural effusions. However, the prevalence of these findings was the same in hospitalized patients without PE. A prominent central pulmonary artery with local oligemia (Westermark sign) or pleural-based areas of increased opacity that represent intraparenchymal hemorrhage (Hampton hump) are uncommon (see x-ray). Paradoxically, the chest radiograph may be most helpful when normal in the setting of hypoxemia.

Fig.

A: Pulmonary embolism (chest radiograph). The heart is significantly enlarged, with prominence of main pulmonary arterial outflow as indicated by fullness in the region of the pulmonary hila. However, there are no other changes in the peripheral lung suggestive of a pulmonary embolus. ***B:*** Pulmonary embolism (pulmonary angiogram). A large embolus is present in the right main pulmonary artery at its point of bifurcation between the upper and middle and the lower lobe vessels, resulting in a paucity of perfusion of vessels distal to the embolus. (Courtesy of H Goldberg.)

Lung scanning

A perfusion scan is performed by injecting radiolabeled microaggregated albumin into the venous system, allowing the particles to embolize to the pulmonary capillary bed. To perform a ventilation scan, the patient breathes a radioactive gas or aerosol while the distribution of radioactivity in the lungs is recorded.

A defect on perfusion scanning represents diminished blood flow to that region of the lung. This finding is not specific for PE. Defects in the perfusion scan are interpreted in conjunction with the ventilation scan to give a high, low, or intermediate (indeterminate) probability that PE is the cause of the abnormalities. Criteria for the combined interpretation of ventilation and perfusion scans (commonly referred to as a single test, the / scan) are complex, confusing, and not completely standardized. A normal perfusion scan excludes the diagnosis of clinically significant PE (negative predictive value of 91% in the PIOPED I study). A high-probability / scan is most often defined as having two or more segmental perfusion defects in the presence of normal ventilation and is sufficient to make the diagnosis of PE in most instances (positive predictive value of 88% among PIOPED I patients).

/ scans are most helpful when they are either normal (see x-ray); (see x-ray) or indicate a high probability of PE. Such readings are reliable—interobserver agreement is best for normal and high-probability scans—and they carry predictive power: The likelihood ratios associated with normal and high-probability scans are 0.10 and 18, respectively, indicating significant and frequently conclusive changes from pretest to posttest probability.

Fig.

Normal lung perfusion. A routine examination may include as many as eight views–anterior, posterior, right and left anterior and posterior obliques, and both right and left laterals (***A*** to ***H***). Some physicians prefer to omit the anterior obliques; others do not include the laterals. There is general agreement that the posterior obliques are the most valuable views. When the patient is injected in the supine position, the radioactive particles are evenly distributed throughout the lungs, with a gently increasing gradient of activity from the upper anterior to the lower posterior lung fields. The cardiac and mediastinal spaces between the lungs have a configuration in the combined anterior and posterior views similar to that of the respective area in the posteroanterior chest radiograph. Cardiomegaly and mediastinal masses will cause distortions that are common to both examinations. An enlarged cardiac space may be caused by cardiomegaly and by effusions or other conditions of the pericardial sac and adjacent pleural cavity. If the patient is rotated, the lung images may override and cause a false defect, which will disappear when the patient is repositioned accurately. However, a true lesion is unlikely if seen in only one view of a complete study. (Reproduced, with permission, from Baum S et al: *Atlas of Nuclear Medicine Imaging*, 2nd ed. Originally published by Appleton & Lange. Copyright © 1992 by The McGraw-Hill Companies, Inc.)

Fig.

Normal lung ventilation with xenon-133. With the patient's single full breath, inhaled radioxenon is evenly distributed to all lung areas, reaching the terminal airways and alveoli in the normal patient (***A,*** posterior view). There is a less noticeable gradient of activity from the upper to the lower lung fields than is seen in perfusion lung images. Fifteen-second images obtained during closed-system rebreathing of a xenon–oxygen mixture show uniform distribution at 120 seconds ***(B)*** . Serial 15-second frames after switching the patient to room air breathing (***C*** to ***G***) show a homogeneous pattern of washout from all lung areas. This sequence mainly evaluates the posterior lung regions. To better localize gas trapping in specific lung segments or more anterior regions, the acquisition may be modified after the rebreathing phase by rotating the patient into posterior oblique positions. Selected images from a complete study include single breath (***H,*** posterior view), the late phase of rebreathing (***I,*** posterior view), posterior washout ***(J)*** , left posterior oblique washout ***(K),*** and right posterior oblique washout ***(L)*** . No gas is retained in this patient, which is normal, but in obstructive airway disease gas retention persists and is better localized in the oblique views than in a posterior view alone. A small amount of alveolar xenon normally crosses the alveolar membrane to reach the blood and be distributed throughout the body. Because it is highly soluble in lipids, xenon accumulates in adipose tissue, including the liver, which is faintly seen with prolonged rebreathing. Liver activity should not be mistaken for delayed washout of xenon from the base of the lung. Occasionally, splenic blood pool radioactivity or swallowed xenon in the stomach may also be seen. (SIN BRE = single breath, L REB = late rebreathe, WO = washout.) (Reproduced, with permission, from Baum S et al: *Atlas of Nuclear Medicine Imaging*, 2nd ed. Originally published by Appleton & Lange. Copyright © 1993 by The McGraw-Hill Companies, Inc.)

However, 75% of PIOPED I / scans were nondiagnostic, ie, of low or intermediate probability. At angiography, these patients had an overall incidence of PE of 14% and 30%, respectively.

One of the most important findings of PIOPED I was that the clinical assessment of pretest probability could be used to aid the interpretation of the / scan. For patients with low-probability / scans and a low (20% or less) clinical pretest probability of PE, the diagnosis was confirmed in only 4%. Such patients may reasonably be observed off therapy without angiography. All other patients with nondiagnostic / scans require further testing to determine the presence of venous thromboembolism.

CT

Helical CT pulmonary angiography has essentially supplanted / scanning as the initial diagnostic study in North America for suspected PE. Helical CT pulmonary angiography requires administration of intravenous radiocontrast dye but is otherwise noninvasive. A high quality study is very sensitive for the detection of thrombus in the proximal pulmonary arteries but less so in more distal arteries where it may miss as many as 75% of subsegmental defects, compared with pulmonary angiography. Comparing helical CT pulmonary angiography to the / scan as the initial test for PE, detection of thrombi is roughly comparable, although more alternative pulmonary diagnoses are made with CT scanning.

Test characteristics of helical CT pulmonary angiography vary widely by study and facility. Factors influencing results include patient size and cooperation, the type and quality of the scanner, the imaging protocol, and the experience of the interpreting radiologist. Early studies comparing single-detector helical CT with standard angiography reported sensitivity of 53–60% and specificity of 81–97% for the diagnosis of PE. The 2006 PIOPED II study, using multidetector (four-row) helical CT and excluding the 6% of patients whose studies were "inconclusive," reported sensitivity of 83% and specificity of 96%.

A 15–20% false-negative rate is high for a screening test, and raises the practical question whether it is safe to withhold anticoagulation in patients with a negative helical CT. Research data provide two complementary answers. The insight of PIOPED I, that the clinical assessment of pretest probability improves the performance of the / scan, was confirmed with helical CT pulmonary angiography in PIOPED II, where positive and negative predictive values were highest in patients with concordant clinical assessments but poor with conflicting assessments: The negative predictive value of a normal helical CT in patients with a high pretest probability was only 60%. Therefore, a normal helical CT alone does not exclude PE in high-risk patients, and either empiric therapy or further testing is indicated.

A large, prospective trial called the Christopher Study incorporated objective, validated pretest clinical assessment into diagnostic algorithms using D-dimer measurement. In this study, patients with a high pretest probability and a negative helical CT pulmonary angiogram who were not receiving anticoagulation had a low (< 2%) 3-month incidence of subsequent PE. This low rate of complications supports the contention that many false-negative studies represent clinically insignificant, small distal thrombi and provides support for monitoring most patients with a high-quality negative helical CT pulmonary angiogram off therapy (see Integrated Approach to Diagnosis of Pulmonary Embolism below). The rate of false-positive helical CT pulmonary angiograms and overtreatment of PE has not been as well studied to date.

Venous thrombosis studies

Seventy percent of patients with PE will have DVT on evaluation, and approximately half of patients with DVT will have PE on angiography. Since the history and physical examination are neither sensitive nor specific for PE and since the results of / scanning are frequently equivocal, documentation of DVT in a patient with suspected PE establishes the need for treatment and may preclude further testing.

Commonly available diagnostic techniques include venous ultrasonography, impedance plethysmography, and contrast venography. In most centers, venous ultrasonography is the test of choice to detect proximal DVT (see echocardiogram). Inability to compress the common femoral or popliteal veins in symptomatic patients is diagnostic of first-episode DVT (positive predictive value of 97%); full compressibility of both sites excludes proximal DVT (negative predictive value of 98%). The test is less accurate in distal thrombi, recurrent thrombi, or in asymptomatic patients. Impedance plethysmography relies on changes in electrical impedance between patent and obstructed veins to determine the presence of thrombus. Accuracy is comparable though not quite as high as ultrasonography. Both ultrasonography and impedance plethysmography are useful in the serial examination of patients with high clinical suspicion of venous thromboembolism but negative leg studies. In patients with suspected first-episode DVT and a negative ultrasound or impedance plethysmography examination, multiple studies have confirmed the safety of withholding anticoagulation while conducting two sequential studies on days 1–3 and 7–10.

Similarly, patients with nondiagnostic / scans and an initial negative venous ultrasound or impedance plethysmography examination may be monitored off therapy with serial leg studies over 2 weeks. When serial examinations are negative for proximal DVT, the risk of subsequent venous thromboembolism over the following 6 months is less than 2%.

Fig.

Deep venous thrombosis. Aged thrombus (T) presents with various degrees of echogenicity. ***A:*** Common femoral vein (C). ***B:*** Popliteal vein (P). (Reproduced, with permission, from Krebs CA, Giyanani VL, Eisenberg RL: *Ultrasound Atlas of Disease Processes*. Originally published by Appleton & Lange. Copyright © 1993 by The McGraw-Hill Companies, Inc.)

Contrast venography remains the reference standard for the diagnosis of DVT (see venogram). An intraluminal filling defect is diagnostic of venous thrombosis.

However, venography has significant shortcomings and has been replaced by venous ultrasound as the diagnostic procedure of choice. Venography may be useful in complex situations where there is discrepancy between clinical suspicion and noninvasive testing.

Fig.

Venography of deep venous thrombosis. Venography demonstrates ***(A)*** a filling defect (*arrow*) and ***(B)*** the "railroad sign" (*arrowhead*). Pulmonary angiography

Pulmonary angiography remains the reference standard for the diagnosis of PE. An intraluminal filling defect in more than one projection establishes a definitive diagnosis. Secondary findings highly suggestive of PE include abrupt arterial cutoff, asymmetry of blood flow—especially segmental oligemia—or a prolonged arterial phase with slow filling. Pulmonary angiography was performed in 755 patients in the PIOPED I study. A definitive diagnosis was established in 97%; in 3% the studies were nondiagnostic. Four patients (0.8%) with negative angiograms subsequently had pulmonary thromboemboli at autopsy. Serial angiography has demonstrated minimal resolution of thrombus prior to day 7 following presentation. Thus, negative angiography within 7 days of presentation excludes the diagnosis.

Pulmonary angiography is a safe but invasive procedure with well-defined morbidity and mortality data. Minor complications occur in approximately 5% of patients. Most are allergic contrast reactions, transient kidney dysfunction, or related to percutaneous catheter insertion; cardiac perforation and arrhythmias are reported but rare. Among the PIOPED I patients who underwent angiography, there were five deaths (0.7%) directly related to the procedure.

The appropriate role of pulmonary angiography in the diagnosis of PE remains a subject of ongoing debate. There is wide agreement that angiography is indicated in any patient in whom the diagnosis is in doubt when there is a high clinical pretest probability of PE or when the diagnosis of PE must be established with certainty, as when anticoagulation is contraindicated or placement of an inferior vena cava filter is contemplated.

MRI

MRI has sensitivity and specificity equivalent to contrast venography in the diagnosis of DVT. It has improved sensitivity when compared with venous ultrasound in the diagnosis of DVT, without loss of specificity. The test is noninvasive and avoids the use of potentially nephrotoxic radiocontrast dye. However, it remains expensive and not widely available. Artifacts introduced by respiratory and cardiac motion have limited the use of MRI in the diagnosis of PE. New techniques have improved sensitivity and specificity to levels comparable with helical CT, but MRI remains primarily a research tool for PE.

Integrated Approach to Diagnosis of Pulmonary Embolism

An integrated approach to diagnosis of PE uses the clinical likelihood of venous thromboembolism derived from a clinical prediction rule (Table 9–16) along with the results of diagnostic tests to come to one of three decision points: to establish venous thromboembolism (PE or DVT) as the diagnosis, to exclude venous thromboembolism with sufficient confidence to follow the patient off anticoagulation, or to refer the patient for additional testing. An ideal diagnostic algorithm would proceed in a cost-effective, stepwise fashion to come to these decision points at minimal risk to the patient. The standard / scan based algorithm (Table 9–17) has been replaced in most North American centers by a rapid D-dimer and helical CT pulmonary angiography based diagnostic algorithm (Figure 9–5: illustration). The / scan remains useful in many patients, especially those who are not able to undergo CT pulmonary angiography (eg, those with advanced chronic kidney disease), but there is a growing evidence to support the CT-based approach. In the rigorously conducted Christopher Study, the incidence of venous thromboembolism was only 1.3% and fatal PE occurred in just 0.5% of persons monitored for 3 months off anticoagulation therapy after objective, validated tools for clinical assessment, quantitative rapid D-dimer assays and a negative helical CT pulmonary angiography. The incidence of PE following a negative evaluation by these three means is comparable to that seen following negative pulmonary angiography.

Table 9–16. Clinical prediction rule for pulmonary embolism (PE).

Variable	**Points**
Clinical symptoms and signs of deep venous thrombosis (DVT) (leg swelling and pain with palpation of deep veins)	3.0
Alternative diagnosis less likely than PE	3.0
Heart rate > 100 beats/min	1.5

Immobilization for more than 3 days or surgery in previous 4 weeks	1.5
Previous PE or DVT	1.5
Hemoptysis	1.0
Cancer (with treatment within past 6 months or palliative care)	1.0
Three-tiered clinical probability assessment	**Score**
High	> 6.0
Moderate	2.0 to 6.0
Low	< 2.0
Dichotomous clinical probability assessment	**Score**

Prevention

Venous thromboembolism is often clinically silent until it presents with significant morbidity or mortality. It is a prevalent disease, clearly associated with identifiable risk factors. For example, the incidence of proximal DVT, PE, and fatal PE in untreated patients undergoing hip fracture surgery is reported to be 10–20%, 4–10%, and 0.2–5%, respectively. There is unambiguous evidence of the efficacy of prophylactic therapy in this and other clinical situations, yet it remains underused. Only about 50% of surgical deaths from PE had received any form of preventive therapy. A discussion of strategies for the prevention of venous thromboembolism can be found in Chapter 14: Disorders of Hemostasis & Antithrombotic Therapy.

Treatment

Anticoagulation

Anticoagulation is not definitive therapy but a form of secondary prevention. Heparin binds to and accelerates the ability of antithrombin to inactivate thrombin, factor Xa, and factor IXa. It thus retards additional thrombus formation, allowing endogenous fibrinolytic mechanisms to lyse existing clot. The standard regimen of heparin followed by 6 months of oral warfarin results in an 80–90% reduction in the risk of both recurrent venous thrombosis and death from PE.

Heparin has troublesome pharmacokinetics. Its clearance is dose-dependent, it is highly protein-bound, and a minimum or threshold level is necessary to achieve an antithrombotic effect. It is necessary to monitor the activated partial thromboplastin time (aPTT) and adjust dosing to maintain the aPTT 1.5–2.5 times control. In patients with a moderate to high clinical likelihood of PE and no contraindications, full anticoagulation with heparin should begin with the diagnostic evaluation. Once the diagnosis of proximal DVT or PE is established, it is critical to ensure adequate therapy. Failure to achieve therapeutic heparin levels within 24 hours is associated with a fivefold increased risk of clot propagation. Heparin causes immune-mediated thrombocytopenia in 3% of patients; therefore, the platelet count should be determined frequently for the first 14 days of therapy. A subcutaneous, weight-adjusted regimen of unfractionated heparin has been proposed as a therapeutic alternative to intravenous or subcutaneous low-molecular-weight heparin (LMWH), when lack of intravenous access or resources prevent the favored approach.

LMWHs are depolymerized preparations of heparin with multiple advantages over unfractionated heparin. They exhibit less binding to cells and proteins and have superior bioavailability, a longer plasma half-life, and more predictable dose-response characteristics. They appear to carry an equivalent or lower risk of hemorrhage, and immune-mediated thrombocytopenia is less common. LMWHs are as effective as unfractionated heparin in the treatment of venous thromboembolism. They are administered in dosages determined by body weight once or twice daily without the need for coagulation monitoring, and subcutaneous administration appears to be as effective as the intravenous route. This profile makes LMWHs ideal for home-based therapy of venous thromboembolism. Home-based therapy appears safe and efficacious in a small number of selected patients. Table 14–13 outlines initial anticoagulation regimens.

Anticoagulation therapy for venous thromboembolism is continued for a minimum of 3 months, so oral anticoagulant therapy with warfarin is usually initiated concurrently with heparin. Warfarin affects hepatic synthesis of vitamin K–dependent coagulant proteins. It usually requires 5–7 days to become therapeutic; therefore, heparin is generally continued for 5 days. Warfarin is safe if begun concurrently with heparin, initially at a dose of 2.5–10 mg/d. The lower dose is preferred in elderly patients. Maintenance therapy usually requires 2–15 mg/d. Adequacy of therapy must be monitored by following the prothrombin time, most often adjusted for differences in reagents and reported as the international normalized ratio (INR). The target INR is

2.5, with the acceptable range from 2.0 to 3.0; below 2.0, there is an increased risk of thrombosis; above 4.0, there is an increased risk of hemorrhage. Warfarin has interactions with many drugs. Meticulous attention to medications is part of the routine management of every patient receiving warfarin. Warfarin is a pregnancy category X medication, indicating known fetopathic and teratogenic effects. When oral anticoagulation with warfarin is contraindicated, LMWH is a convenient alternative.

The optimal duration of anticoagulation therapy for venous thromboembolism is unknown. There appears to be a protective benefit to continued anticoagulation in first-episode venous thromboembolism (twice the rate of recurrence in 6 weeks compared with 6 months of therapy) and recurrent disease (eightfold risk of recurrence in 6 months compared with 4 years of therapy). These studies do not distinguish patients with reversible risk factors, such as surgery or transient immobility, from patients who have a nonreversible hypercoagulable state such as factor V Leiden, inhibitor deficiency, antiphospholipid syndrome, or malignancy. A RCT of low-dose warfarin (INR 1.5–2.0) versus no therapy following 6 months of standard therapy in patients with idiopathic DVT was stopped early. The protective benefits of continued anticoagulation include fewer DVTs in addition to a trend toward lower mortality despite more hemorrhage in the warfarin group. Risk reductions were consistent across groups with and without inherited thrombophilia.

For many patients, venous thrombosis is a recurrent disease, and continued therapy results in a lower rate of recurrence at the cost of an increased risk of hemorrhage. Therefore, the appropriate duration of therapy needs to take into consideration potentially reversible risk factors, the individual's age, the likelihood and potential consequences of hemorrhage, and patient preferences for continued therapy. It is reasonable to continue therapy for 6 months after a first episode when there is a reversible risk factor, 12 months after a first-episode of idiopathic thrombosis, and 6–12 months to indefinitely in patients with nonreversible risk factors or recurrent disease. The optimal duration of therapy has not been established, but D-dimer testing has been suggested to have a role in identifying those who may benefit from continued anticoagulation after 3 months of therapy. This is an area of active research.

The major complication of anticoagulation is hemorrhage. Risk factors for hemorrhage include the intensity of the anticoagulant effect; the duration of therapy; concomitant administration of drugs such as aspirin that interfere with platelet function; and patient characteristics, particularly increased age, previous gastrointestinal hemorrhage, and coexistent chronic kidney disease.

The reported incidence of major hemorrhage following intravenous administration of unfractionated heparin is nil to 7%; that of fatal hemorrhage is nil to 2%. The incidence with LMWHs is not statistically different. There is no information comparing hemorrhage rates at different doses of heparin. The risk of subtherapeutic heparin administration in the first 24–48 hours after diagnosis is significant; it appears to outweigh the risk of short-term supratherapeutic heparin levels. The incidence of hemorrhage during therapy with warfarin is reported to be between 3% and 4% per patient year. The frequency varies with the target INR and is consistently higher when the INR exceeds 4.0. There is no apparent additional antithrombotic benefit in venous thromboembolism with a target INR above 2.0–3.0 (see Chapter 14: Disorders of Hemostasis & Antithrombotic Therapy).

Thrombolytic Therapy

Streptokinase, urokinase, and recombinant tissue plasminogen activator (rt-PA; alteplase) increase plasmin levels and thereby directly lyse intravascular thrombi. In patients with established PE, thrombolytic therapy accelerates resolution of emboli within the first 24 hours compared with standard heparin therapy. This is a consistent finding using angiography, [/] scanning, echocardiography, and direct measurement of pulmonary artery pressures. However, at 1 week and 1 month after diagnosis, these agents show no difference in outcome compared with heparin and warfarin. There is no evidence that thrombolytic therapy improves mortality. Subtle improvements in pulmonary function, including improved single-breath diffusing capacity and a lower incidence of exercise-induced pulmonary hypertension, have been observed. The reliability and clinical importance of these findings is unclear. The major disadvantages of thrombolytic therapy compared with heparin are its greater cost and a significant increase in major hemorrhagic complications. The incidence of intracranial hemorrhage in patients with PE treated with alteplase is 2.1% compared with 0.2% in patients treated with heparin.

Current evidence supports thrombolytic therapy for PE in patients at high risk for death in whom the more rapid resolution of thrombus may be lifesaving. Such patients are usually hemodynamically unstable despite heparin therapy. Absolute contraindications to thrombolytic therapy include active internal bleeding and stroke within the past 2 months. Major contraindications include uncontrolled hypertension and surgery or trauma within the past 6 weeks. The role of thrombolysis in patients who are hemodynamically stable but with echocardiographic evidence of right heart strain is unclear and is subject to considerable practice variation.

Additional Measures

Interruption of the inferior vena cava may be indicated in patients with a major contraindication to anticoagulation who have or are at high risk for development of proximal DVT or PE. Placement of an inferior vena cava filter is also recommended for recurrent thromboembolism despite adequate anticoagulation, for chronic recurrent embolism with a compromised pulmonary vascular bed (eg, in pulmonary hypertension), and with the concurrent performance of surgical pulmonary embolectomy or pulmonary thromboendarterectomy. Percutaneous transjugular placement of a mechanical filter is the preferred mode of inferior vena cava interruption. These devices reduce the short-term incidence of PE in patients presenting with proximal lower extremity DVT. However, they are associated with a twofold increased risk of recurrent DVT in the first 2 years following placement.

In rare critically ill patients for whom thrombolytic therapy is contraindicated or unsuccessful, mechanical or surgical extraction of thrombus may be indicated. Pulmonary embolectomy is an emergency procedure of last resort with a very high mortality rate. It is now performed only in a few specialized centers. Several catheter devices to fragment and extract thrombus through a transvenous approach have been reported in small numbers of patients. Comparative outcomes with surgery, thrombolytic therapy, or heparin have not been studied.

Prognosis

PE is estimated to cause more than 50,000 deaths annually. In the majority of deaths, PE is not recognized antemortem or death occurs before specific treatment can be initiated. These statistics highlight the importance of preventive therapy in high-risk patients (Chapter 14: Disorders of Hemostasis & Antithrombotic Therapy). The outlook for patients with diagnosed and appropriately treated PE is generally good. Overall prognosis depends on the underlying disease rather than the PE itself. Death from recurrent thromboemboli is uncommon, occurring in less than 3% of cases. Perfusion defects resolve in most survivors. Chronic thromboembolic pulmonary hypertension develops in approximately 1% of patients. Selected patients may benefit from pulmonary endarterectomy.

Pulmonary Hypertension

Essentials of Diagnosis

- Dyspnea, fatigue, chest pain, and syncope on exertion.
- Narrow splitting of second heart sound with loud pulmonary component; findings of right ventricular hypertrophy and cardiac failure in advanced disease.
- Hypoxemia and increased wasted ventilation on pulmonary function tests.

- Electrocardiographic evidence of right ventricular strain or hypertrophy and right atrial enlargement.
- Enlarged central pulmonary arteries on chest radiograph.

General Considerations

The pulmonary circulation is unique because of its high blood flow, low pressure (normally 25/8 mm Hg, mean 12), and low resistance (normally 200–250 dynes/sec/cm^{-5}). It can accommodate large increases in blood flow during exercise with only modest increases in pressure because of its ability to recruit and distend lung blood vessels. Contraction of smooth muscle in the walls of pulmonary arteriolar resistance vessels becomes an important factor in numerous pathologic states. Pulmonary hypertension is present when pulmonary artery pressure rises to a level inappropriate for a given cardiac output. Once present, pulmonary hypertension is self-perpetuating. It introduces secondary structural abnormalities in pulmonary vessels, including smooth muscle hypertrophy and intimal proliferation, and these may eventually stimulate atheromatous changes and in situ thrombosis, leading to further narrowing of the arterial bed.

Selected mechanisms responsible for **secondary pulmonary hypertension** and examples of corresponding clinical conditions are set forth in Table 9–18. Pulmonary arteriolar vasoconstriction due to chronic hypoxemia may complicate any chronic lung disease and compound the effects of loss of pulmonary blood vessels (as seen with disorders such as emphysema and pulmonary fibrosis) and obstruction of the pulmonary vascular bed (as seen with disorders such as chronic pulmonary thromboembolic disease). Sustained increases in pulmonary venous pressure from left ventricular failure (systolic, diastolic, or both), mitral stenosis, and pulmonary veno-occlusive disease may cause "postcapillary" pulmonary hypertension. Increased pulmonary blood flow due to intracardiac shunts and increased blood viscosity due to polycythemia can also cause pulmonary hypertension. Pulmonary hypertension has also been associated with hepatic cirrhosis and portal hypertension.

Table 9–18. Mechanisms of pulmonary hypertension and examples of corresponding clinical conditions.
Reduction in cross-sectional area of pulmonary arterial bed
Vasoconstriction
Hypoxemia from any cause (chronic lung disease, sleep-disordered breathing, etc)
Acidosis

Loss of vessels
Lung resection
Emphysema
Vasculitis
Interstitial lung disease
Collagen-vascular disease
Obstruction of vessels
Pulmonary embolism (thromboemboli, tumor emboli, etc)
In situ thrombosis
Schistosomiasis
Sickle cell disease
Narrowing of vessels
Secondary structural changes due to pulmonary hypertension
Increased pulmonary venous pressure
Constrictive pericarditis
Left ventricular failure or reduced compliance
Mitral stenosis
Left atrial myxoma
Pulmonary veno-occlusive disease
Mediastinal diseases compressing pulmonary veins
Increased pulmonary blood flow

Congenital left-to-right intracardiac shunts
Increased blood viscosity
Polycythemia
Miscellaneous
Pulmonary hypertension occurring in association with hepatic cirrhosis and portal hypertension
HIV infection

Idiopathic (formerly **primary**) **pulmonary hypertension** (see Chapter 10: Heart Disease) is pulmonary arterial hypertension that occurs in the absence of the identified cardiopulmonary disorders above or significant connective tissue disease. It occurs with hepatic cirrhosis and portal hypertension, HIV infection, use of anorectic drugs and sporadically in young and middle-aged women, some of whom have a familial form. Untreated, it is characterized by progressive dyspnea, a rapid downhill course, and an invariably fatal outcome. This condition is also called **plexogenic pulmonary arteriopathy,** in reference to the characteristic histopathologic plexiform lesion found in muscular pulmonary arteries.

Pulmonary veno-occlusive disease is a rare cause of postcapillary pulmonary hypertension occurring in children and young adults. The cause is unknown, but associations with various conditions such as viral infection, bone marrow transplantation, chemotherapy, and malignancy have been described. The disease is characterized by progressive fibrotic occlusion of pulmonary veins and venules, along with secondary hypertensive changes in the pulmonary arterioles and muscular pulmonary arteries. Nodular areas of pulmonary congestion, edema, hemorrhage, and hemosiderosis are found. Chest radiography reveals prominent, symmetric interstitial markings, Kerley B lines, pulmonary artery dilation, and normally sized left atrium and left ventricle. Antemortem diagnosis is often difficult but is occasionally established by open lung biopsy. There is no effective therapy, and most patients die within 2 years as a result of progressive pulmonary hypertension.

Clinical Findings

Symptoms and Signs

Secondary pulmonary hypertension is difficult to recognize clinically in the early stages, when symptoms and signs are primarily those of the underlying disease. Pulmonary hypertension may cause or contribute to dyspnea, present initially on exertion and later at rest. Dull, retrosternal chest pain resembling angina pectoris may be present. Fatigue and syncope on exertion also occur, presumably a result of reduced cardiac output related to elevated pulmonary artery pressures or bradycardia.

The signs of pulmonary hypertension include narrow splitting of the second heart sound, accentuation of the pulmonary component of the second heart sound, and a systolic ejection click. In advanced cases, tricuspid and pulmonary valve insufficiency and signs of right ventricular failure and cor pulmonale are found.

Laboratory Findings

Polycythemia is found in many cases of pulmonary hypertension that are associated with chronic hypoxemia. Electrocardiographic changes are those of right axis deviation, right ventricular hypertrophy, right ventricular strain, or right atrial enlargement (see ECG).

Fig.

ECG from a patient with primary pulmonary hypertension, showing severe right ventricular hypertrophy. Note the monophasic tall R preceded by a small Q in V_1 and the small R and deep S in V_6. The P wave in V_1 is upright and directed anteriorly, indicating right atrial hypertrophy, and there is also right axis deviation with a deep S in lead I and a tall R in lead III. Imaging and Special Examinations

Radiographs and high-resolution CT scans of the chest can assist in the diagnosis of pulmonary hypertension and determination of the cause. In chronic disease, dilation of the right and left main and lobar pulmonary arteries and enlargement of the pulmonary outflow tract are seen; in advanced disease, right ventricular and right atrial enlargement are seen (see x-ray). Peripheral "pruning" of large pulmonary arteries is characteristic of pulmonary hypertension in severe emphysema.

Echocardiography is helpful in evaluating patients thought to have mitral stenosis, left atrial myxoma, and pulmonary valvular disease and may also reveal right ventricular enlargement and paradoxical motion of the interventricular septum (see Video). Doppler ultrasonography is a reliable noninvasive means of estimating pulmonary artery systolic pressure. However, precise hemodynamic measurements can only be obtained with right heart catheterization, which is helpful when postcapillary pulmonary hypertension, intracardiac shunting, or thromboembolic disease is considered as part of the differential diagnosis.

Video 9-1

Paradoxical septal motion. (Courtesy of E Foster.)

The diagnosis of pulmonary hypertension cannot be made on routine pulmonary function tests. Some results may help identify the cause; eg, diminution of the pulmonary capillary bed may cause reduction in the single breath diffusing capacity.

The following studies may be useful to exclude causes of secondary pulmonary hypertension: liver function tests, HIV test, collagen-vascular serologic studies, polysomnography, / lung scanning, pulmonary angiography, and surgical lung biopsy. / lung scanning is very helpful in identifying patients with pulmonary hypertension caused by recurrent pulmonary thromboemboli (see x-ray), a condition that is often difficult to recognize clinically.

Fig.

Recurrence of pulmonary embolism over a long time. There are multiple segmental perfusion defects (***A*** to ***D***) that are normal on ventilation (***E*** to ***F*** , posterior views), introducing a high probability of pulmonary embolism. Thirteen days later, the perfusion study shows virtually complete resolution (***G*** to ***J***). The patient returned 28 months later with bilateral perfusion defects (***K*** to ***N***), with normal ventilation and a normal chest radiograph (not shown), which is compatible with recurrent pulmonary embolism. Extensive defects are again seen 51/2 years later (***O*** to ***R***), with only minor trapping of xenon in the lung bases (***S*** to ***V***), indicating recurrent pulmonary embolism. Partial resolution is seen 9 days later (***W*** to ***Z***). (REB = rebreathe, WO = washout, SIN BRE = single breath.) Treatment

Treatment of idiopathic (primary) pulmonary hypertension is discussed in Chapter 10: Heart Disease. Treatment of secondary pulmonary hypertension consists mainly of treating the underlying disorder. Early recognition of pulmonary hypertension is crucial to interrupt the self-perpetuating cycle responsible for rapid clinical progression. Most patients who present with symptoms and signs of pulmonary hypertension, however, already have advanced disease. If hypoxemia or acidosis is detected, corrective measures should be started immediately. Supplemental oxygen administered for at least 15 hours per day has been demonstrated to slow the progression of pulmonary hypertension in patients with hypoxemic COPD.

Permanent anticoagulation is indicated in idiopathic pulmonary hypertension but should be given only to those patients with secondary pulmonary hypertension at high risk for thromboembolism. Vasodilator therapy using various pharmacologic agents (eg, calcium antagonists, hydralazine, isoproterenol, diazoxide, nitroglycerin) has shown disappointing results in secondary pulmonary hypertension. Patients most likely to benefit from long-term pulmonary vasodilator therapy are those who respond favorably to a vasodilator challenge at right heart catheterization. It is clear that long-term oral vasodilator therapy should be used only if hemodynamic benefit is documented. Complications of pulmonary vasodilator therapy include systemic hypotension, hypoxemia, and even death.

Continuous long-term intravenous infusion (using a portable pump) of prostacyclin (PGI_2; epoprostenol), a potent pulmonary vasodilator, has been shown to confer hemodynamic and symptomatic benefits in selected patients with idiopathic pulmonary hypertension. This is the first therapy to demonstrate improved survival of patients with idiopathic pulmonary hypertension. Limitations of continuous infusion prostacyclin are difficulties in titration, technical problems with portable delivery systems, and the high cost of the drug. Newer agents in research trials include subcutaneous (treprostinil), inhaled (iloprost), and oral (beraprost) prostacyclin analogues, endothelin receptor antagonists (bosentan), and phosphodiesterase inhibitors (sildenafil). Some of these agents have shown improvement in functional status but, so far, there is no evidence for improved outcomes. Combination therapy is an area of active research.

Patients with marked polycythemia (hematocrit > 60%) should undergo repeated phlebotomy in an attempt to reduce blood viscosity. Cor pulmonale complicating pulmonary hypertension is treated by managing the underlying pulmonary disease and by using diuretics, salt restriction, and, in appropriate patients, supplemental oxygen. The use of digitalis in cor pulmonale remains controversial. Pulmonary thromboendarterectomy may benefit selected patients with pulmonary hypertension secondary to chronic thrombotic obstructions of major pulmonary arteries.

Single or double lung transplantation may be performed on patients with end-stage idiopathic (primary) pulmonary hypertension. The 2-year survival rate is 50%.

Prognosis

The prognosis in secondary pulmonary hypertension depends on the course of the underlying disease. The prognosis is favorable when pulmonary hypertension is detected early and the conditions leading to it are readily reversed. Patients with pulmonary hypertension due to fixed obliteration of the pulmonary vascular bed generally respond poorly to therapy; development of cor pulmonale in these cases implies a poor prognosis.

Pulmonary Vasculitis

Wegener granulomatosis is an idiopathic disease manifested by a combination of glomerulonephritis, necrotizing granulomatous vasculitis of the upper and lower respiratory tracts, and varying degrees of small vessel vasculitis. Chronic sinusitis, arthralgias, fever, skin rash, and weight loss are frequent presenting symptoms. Specific pulmonary complaints occur less often. The most common sign of lung disease is nodular pulmonary infiltrates, often with cavitation, seen on chest radiography. Tracheal stenosis and endobronchial disease are sometimes seen. The diagnosis is most often based on serologic testing and biopsy of lung, sinus tissue, or kidney with demonstration of necrotizing granulomatous vasculitis. See Chapter 19: Musculoskeletal & Immunologic Disorders.

Allergic angiitis and granulomatosis (Churg-Strauss syndrome) is an idiopathic multisystem vasculitis of small and medium-sized arteries that occurs in patients with asthma. Histologic features include fibrinoid necrotizing epithelioid and eosinophilic granulomas. The skin and lungs are most often involved, but other organs, including the paranasal sinuses, the heart, gastrointestinal tract, liver, and peripheral nerves, may also be affected. Peripheral eosinophilia > 1500 cells/mcL or > 10% of peripheral WBCs is the rule. Abnormalities on chest radiographs range from transient infiltrates to multiple nodules. This illness may be part of a spectrum that includes polyarteritis nodosa.

Treatment of pulmonary vasculitis usually requires corticosteroids and cyclophosphamide. Oral prednisone (1 mg/kg ideal body weight per day initially, tapering slowly to alternate-day therapy over 3–6 months) is the corticosteroid of choice; in Wegener granulomatosis, some clinicians may use cyclophosphamide alone. For fulminant vasculitis, therapy may be initiated with intravenous methylprednisolone (up to 1 g intravenously per day) for several days. Cyclophosphamide (1–2 mg/kg ideal body weight per day initially, with dosage adjustments to avoid neutropenia) is given daily by mouth until complete remission is obtained and then is slowly tapered, and often replaced with methotrexate or azathioprine for maintenance therapy.

Five-year survival rates in patients with these vasculitis syndromes have been improved by the combination therapy. Complete remissions can be achieved in over 90% of patients with Wegener granulomatosis. The addition of trimethoprim-sulfamethoxazole (one double-strength tablet by mouth twice daily) to standard therapy may help prevent relapses.

Alveolar Hemorrhage Syndromes

Diffuse alveolar hemorrhage may occur in a variety of immune and nonimmune disorders. Hemoptysis, alveolar infiltrates on chest radiograph, anemia, dyspnea, and occasionally fever are characteristic. Rapid clearing of diffuse lung infiltrates within 2 days is a clue to the diagnosis of diffuse alveolar hemorrhage. Pulmonary hemorrhage can be associated with an increased DL_{CO} .

Causes of **immune alveolar hemorrhage** have been classified as anti-basement membrane antibody disease (Goodpasture syndrome), vasculitis and collagen vascular disease (systemic lupus erythematosus, Wegener granulomatosis, systemic necrotizing vasculitis, and others), and pulmonary capillaritis associated with idiopathic rapidly progressive glomerulonephritis. **Nonimmune causes** of diffuse hemorrhage include coagulopathy, mitral stenosis, necrotizing pulmonary infection, drugs (penicillamine), toxins (trimellitic anhydride), and idiopathic pulmonary hemosiderosis.

Goodpasture syndrome is idiopathic recurrent alveolar hemorrhage and rapidly progressive glomerulonephritis. The disease is mediated by anti-glomerular basement membrane antibodies. Goodpasture syndrome occurs mainly in men who are in their 30s and 40s. Hemoptysis is the usual presenting symptom, but pulmonary hemorrhage may be occult. Dyspnea, cough, hypoxemia, and diffuse bilateral alveolar infiltrates are typical features. Iron deficiency anemia and microscopic hematuria are usually present. The diagnosis is based on characteristic linear IgG deposits in glomeruli or alveoli by immunofluorescence and on the presence of anti-glomerular basement membrane antibody in serum. Combinations of immunosuppressive drugs (initially methylprednisolone, 30 mg/kg intravenously over 20 minutes every other day for three doses, followed by daily oral prednisone, 1 mg/kg/d; with cyclophosphamide, 2 mg/kg by mouth per day) and plasmapheresis have yielded excellent results.

Idiopathic pulmonary hemosiderosis is a disease of children or young adults characterized by recurrent pulmonary hemorrhage; in contrast to Goodpasture syndrome, renal involvement and anti-glomerular basement membrane antibodies are absent, but iron deficiency is typical. Treatment of acute episodes of hemorrhage with corticosteroids may be useful. Recurrent episodes of pulmonary hemorrhage may result in interstitial fibrosis and pulmonary failure.

Bronconeumol. 2008 Aug;44(8):428–36. Spanish. [PMID: 18775255]

Smoke Inhalation

The inhalation of products of combustion may cause serious respiratory complications. As many as one-third of patients admitted to burn treatment units have pulmonary injury from smoke inhalation. Morbidity and mortality due to smoke inhalation exceed those attributed to the burns themselves. The death rate of patients with both severe burns and smoke inhalation exceeds 50%.

All patients suspected of having significant smoke inhalation must be assessed for three consequences of smoke inhalation: impaired tissue oxygenation, thermal injury to the upper airway, and chemical injury to the lung. Impaired tissue oxygenation results from inhalation of carbon monoxide or cyanide and is an immediate threat to life. The management of patients with carbon monoxide and cyanide poisoning is discussed in Chapter 38: Poisoning. The clinician must recognize that patients with carbon monoxide poisoning display a normal partial pressure of oxygen in arterial blood (PaO_2) but have a low *measured* (ie, not oximetric) hemoglobin saturation (SaO_2). Immediate treatment with 100% oxygen is essential and should be continued until the measured carboxyhemoglobin level falls to less than 10% and concomitant metabolic acidosis has resolved.

Thermal injury to the mucosal surfaces of the upper airway occurs from inhalation of hot gases. Complications become evident by 18–24 hours. These include edema, impaired ability to clear oral secretions, and upper airway obstruction, producing inspiratory stridor. Respiratory failure occurs in severe cases. Early management (see also Chapter 37: Disorders Due to Physical Agents) includes the use of a high-humidity face mask with supplemental oxygen, gentle suctioning to evacuate oral secretions, elevation of the head 30 degrees to promote clearing of secretions, and topical epinephrine to reduce edema of the oropharyngeal mucous membrane. Helium-oxygen gas mixtures (Heliox) may reduce labored breathing due to upper airway narrowing. Close monitoring with arterial blood gases and later with oximetry is important. Examination of the upper airway with a fiberoptic laryngoscope or bronchoscope is superior to routine physical examination (see bronchoscopy). Endotracheal intubation is often necessary to establish airway patency and is likely to be necessary in patients with deep facial burns or oropharyngeal or laryngeal edema. Tracheotomy should be avoided if possible because of an increased risk of pneumonia and death from sepsis.

Fig.

These are the findings–48 hours after the event–of the middle lobe bronchus of a 19-year-old male, a paint thinner addict, who attempted suicide by igniting inhaled paint thinner. At the bifurcation, blackening can be seen as well as whitish necrosis and edematous swelling. The widening of the bifurcation due to swelling is characteristic of the initial period following severe airway burns. (Reproduced, with permission, from Oho K, Amemiya R: *Practical Fiberoptic Bronchoscopy*. Igaku-Shoin, 1980.)

Chemical injury to the lung results from inhalation of toxic gases and products of combustion, including aldehydes and organic acids. The site of lung injury depends on the solubility of the gases inhaled, the duration of exposure, and the size of inhaled particles that transport noxious gases to distal lung units. Bronchorrhea and bronchospasm are seen early after exposure along with dyspnea, tachypnea, and tachycardia. Labored breathing and cyanosis may follow. Physical examination at this stage reveals diffuse wheezing and rhonchi. Bronchiolar and alveolar edema (eg, ARDS) may develop within 1–2 days after exposure. Sloughing of the bronchiolar mucosa may occur within 2–3 days, leading to airway obstruction, atelectasis, and worsening hypoxemia. Bacterial colonization and pneumonia are common by 5–7 days after the exposure.

Treatment of smoke inhalation consists of supplemental oxygen, bronchodilators, suctioning of mucosal debris and mucopurulent secretions via an indwelling endotracheal tube, chest physical therapy to aid clearance of secretions, and adequate humidification of inspired gases. Positive end-expiratory pressure (PEEP) has been advocated to treat bronchiolar edema. Judicious fluid management and close monitoring for secondary bacterial infection with daily sputum Gram stains round out the management protocol.

The routine use of corticosteroids for chemical lung injury from smoke inhalation has been shown to be ineffective and may even be harmful. Routine or prophylactic use of antibiotics is not recommended.

Patients who survive should be watched for the late development of bronchiolitis obliterans.

Pulmonary Aspiration Syndromes

Aspiration of foreign material into the tracheobronchial tree results from various disorders that impair normal deglutition, especially disturbances of consciousness and esophageal dysfunction.

Aspiration of Inert Material

Aspiration of inert material may cause asphyxia if the amount aspirated is massive and if cough is impaired, in which case immediate tracheobronchial suctioning is necessary. Most patients suffer no serious sequelae from aspiration of inert material.

Aspiration of Toxic Material

Aspiration of toxic material into the lung usually results in clinically evident pneumonia. **Hydrocarbon pneumonitis** is caused by aspiration of ingested petroleum distillates, eg, gasoline, kerosene, furniture polish, and other household petroleum products. Lung injury results mainly from vomiting and secondary aspiration. Therapy is supportive. The lung should be protected from repeated aspiration with a cuffed endotracheal tube if necessary. **Lipoid pneumonia** is a chronic syndrome related to the repeated aspiration of oily materials, eg, mineral oil, cod liver oil, and oily nose drops; it often occurs in elderly patients with impaired swallowing. Patchy infiltrates in dependent lung zones and lipid-laden macrophages in expectorated sputum are characteristic findings.

"Café Coronary"

Acute obstruction of the upper airway by food is associated with difficulty swallowing, old age, dental problems that impair chewing, and use of alcohol and sedative drugs. The Heimlich procedure is lifesaving in many cases.

Retention of an Aspirated Foreign Body

Retention of an aspirated foreign body in the tracheobronchial tree may produce both acute and chronic conditions, including recurrent pneumonia, bronchiectasis, lung abscess, atelectasis, and postobstructive hyperinflation. Occasionally, a misdiagnosis of asthma, COPD, or lung cancer is made in adult patients who have aspirated a foreign body. The plain chest radiograph usually suggests the site of the foreign body. In some cases, an expiratory film, demonstrating regional hyperinflation due to a check-valve effect, is helpful. Bronchoscopy is usually necessary to establish the diagnosis and attempt removal of the foreign body.

Chronic Aspiration of Gastric Contents

Chronic aspiration of gastric contents may result from primary disorders of the larynx or the esophagus, such as achalasia, esophageal stricture, systemic sclerosis (scleroderma), esophageal carcinoma, esophagitis, and gastroesophageal reflux. In the last condition, relaxation of the tone of the lower esophageal sphincter allows reflux of gastric contents into the esophagus and predisposes to chronic pulmonary aspiration, especially at night. Cigarette smoking, consumption of alcohol, and use of theophylline are known to relax the lower esophageal sphincter. Pulmonary disorders linked to gastroesophageal reflux and chronic aspiration include bronchial asthma, pulmonary fibrosis, and bronchiectasis. Even in the absence of aspiration, acid in the esophagus may trigger bronchospasm through reflex mechanisms.

The diagnosis of chronic aspiration is difficult. Ambulatory monitoring of esophageal pH for 24 hours detects esophageal reflux. Esophagogastroscopy and barium swallow are sometimes necessary to rule out esophageal disease. Management consists of elevation of the head of the bed, cessation of smoking, weight reduction, and antacids, H_2-receptor antagonists (eg, cimetidine, 300–400 mg), or proton pump inhibitors (eg, omeprazole, 20 mg) at night. Metoclopramide (10–15 mg orally four times daily or 20 mg at bedtime), or bethanechol (10–25 mg at bedtime) may also be helpful in some patients with gastroesophageal reflux.

Acute Aspiration of Gastric Contents (Mendelson Syndrome)

Acute aspiration of gastric contents is often catastrophic. The pulmonary response depends on the characteristics and amount of the gastric contents aspirated. The more acidic the material, the greater the degree of chemical pneumonitis. Aspiration of pure gastric acid (pH < 2.5) causes extensive desquamation of the bronchial epithelium, bronchiolitis, hemorrhage, and pulmonary edema. Acute gastric aspiration is one of the most common causes of ARDS. The clinical picture is one of abrupt onset of respiratory distress, with cough, wheezing, fever, and tachypnea. Crackles are audible at the bases of the lungs. Hypoxemia may be noted immediately after aspiration occurs. Radiographic abnormalities, consisting of patchy alveolar infiltrates in dependent lung zones, appear within a few hours. If particulate food matter has been aspirated along with gastric acid, radiographic features of bronchial obstruction may be observed. Fever and leukocytosis are common even in the absence of superinfection.

Treatment of acute aspiration of gastric contents consists of supplemental oxygen, measures to maintain the airway, and the usual measures for treatment of acute respiratory failure. There is no evidence to support the routine use of corticosteroids or prophylactic antibiotics after gastric aspiration has occurred. Secondary pulmonary infection, which occurs in about one-fourth of patients, typically appears 2–3 days after aspiration. Management of this complication depends on the observed flora of the tracheobronchial tree. Hypotension secondary to alveolocapillary membrane injury and intravascular volume depletion is common and is managed with the judicious administration of intravenous fluids.

Occupational Pulmonary Diseases

Many acute and chronic pulmonary diseases are directly related to inhalation of noxious substances encountered in the workplace. Disorders that are due to chemical agents may be classified as follows: (1) pneumoconioses, (2) hypersensitivity pneumonitis, (3) obstructive airway disorders, (4) toxic lung injury, (5) lung cancer, (6) pleural diseases, and (7) miscellaneous disorders.

Pneumoconioses

Pneumoconioses are chronic fibrotic lung diseases caused by the inhalation of coal dust and various other inert, inorganic, or silicate dusts (Table 9–19). Pneumoconioses due to inhalation of inert dusts may be asymptomatic disorders with diffuse nodular infiltrates on chest radiograph. Clinically important pneumoconioses include coal worker's pneumoconiosis, silicosis, and asbestosis. Treatment for each is supportive.

Table 9–19. Selected pneumoconioses.

Disease	Agent	Occupations
Metal dusts		
Siderosis	Metallic iron or iron oxide	Mining, welding, foundry work
Stannosis	Tin, tin oxide	Mining, tin-working, smelting
Baritosis	Barium salts	Glass and insecticide manufacturing
Coal dust		
Coal worker's pneumoconiosis	Coal dust	Coal mining
Inorganic dusts		
Silicosis	Free silica (silicon dioxide)	Rock mining, quarrying, stone cutting, tunneling, sandblasting, pottery, diatomaceous earth
Silicate dusts		
Asbestosis	Asbestos	Mining, insulation, construction, shipbuilding
Talcosis	Magnesium silicate	Mining, insulation, construction, shipbuilding
Kaolin	Sand, mica,	Mining of china clay;

pneumoconiosis	aluminum silicate	pottery and cement work
Shaver disease	Aluminum powder	Manufacture of corundum

Coal Worker's Pneumoconiosis

In coal worker's pneumoconiosis, ingestion of inhaled coal dust by alveolar macrophages leads to the formation of coal macules, usually 2–5 mm in diameter, that appear on chest radiograph as diffuse small opacities that are especially prominent in the upper lung. Simple coal worker's pneumoconiosis is usually asymptomatic; pulmonary function abnormalities are unimpressive. Cigarette smoking does not increase the prevalence of coal worker's pneumoconiosis but may have an additive detrimental effect on ventilatory function. In complicated coal worker's pneumoconiosis (**"progressive massive fibrosis"**), conglomeration and contraction in the upper lung zones occur, with radiographic features resembling complicated silicosis. **Caplan syndrome** is a rare condition characterized by the presence of necrobiotic rheumatoid nodules (1–5 cm in diameter) in the periphery of the lung in coal workers with rheumatoid arthritis.

Silicosis

In silicosis, extensive or prolonged inhalation of free silica (silicon dioxide) particles in the respirable range

(0.3–5 mcm) causes the formation of small rounded opacities (silicotic nodules) throughout the lung (see x-ray). Calcification of the periphery of hilar lymph nodes ("eggshell" calcification) is an unusual radiographic finding that strongly suggests silicosis. Simple silicosis is usually asymptomatic and has no effect on routine pulmonary function tests; in complicated silicosis, large conglomerate densities appear in the upper lung and are accompanied by dyspnea and obstructive and restrictive pulmonary dysfunction. The incidence of pulmonary tuberculosis is increased in patients with silicosis. All patients with silicosis should have a tuberculin skin test and a current chest radiograph. If old, healed pulmonary tuberculosis is suspected, multidrug treatment for tuberculosis (not single-agent preventive therapy) should be instituted.

Fig.

Pulmonary silicosis. (Courtesy of H Goldberg.)

Asbestosis

Asbestosis is a nodular interstitial fibrosis occurring in workers exposed to asbestos fibers (shipyard and construction workers, pipe fitters, insulators) over many years (typically 10–20 years). Patients with asbestosis usually seek medical attention at least 15 years after exposure with the following symptoms and signs: progressive dyspnea, inspiratory crackles, and in some cases, clubbing and cyanosis. The radiographic features of asbestosis include linear streaking at the lung bases, opacities of various shapes and sizes, and honeycomb changes in advanced cases (see x-ray). The presence of pleural calcifications may be a clue to diagnosis. High-resolution CT scanning is the best imaging method for asbestosis because of its ability to detect parenchymal fibrosis and define the presence of coexisting pleural plaques. Cigarette smoking in asbestos workers increases the prevalence of radiographic pleural and parenchymal changes and markedly increases the incidence of lung carcinoma. It may also interfere with the clearance of short asbestos fibers from the lung. Pulmonary function studies show restrictive dysfunction and reduced diffusing capacity. The presence of a ferruginous body in tissue suggests significant asbestos exposure; however, other histologic features must be present for diagnosis. There is no specific treatment.

Fig.
Asbestosis. Calcified pleural plaques at both lung bases

are typical. (Courtesy of H Goldberg.)

Scarisbrick D. Silicosis and coal workers' pneumoconiosis. Practitioner. 2002 Feb;246(1631):114, 117–9. [PMID: 11852619]

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis (also called extrinsic allergic alveolitis) is a nonatopic, nonasthmatic allergic pulmonary disease. It is manifested mainly as an occupational disease (Table 9–20), in which exposure to inhaled organic antigens leads to an acute illness characterized by sudden onset of malaise, chills, fever, cough, dyspnea, and nausea 4–8 hours after exposure to the offending antigen. This may occur after the patient has left work or even at night and thus may mimic paroxysmal nocturnal dyspnea. Bibasilar crackles, tachypnea, tachycardia, and (occasionally) cyanosis are noted. Small nodular densities sparing the apices and bases of the lungs are noted on chest radiograph. Pulmonary function studies reveal restrictive dysfunction and reduced diffusing capacity. Laboratory studies reveal an increase in the white blood cell count with a shift to the left, hypoxemia, and the presence of precipitating antibodies to the offending agent in serum. Hypersensitivity pneumonitis antibody panels against common offending antigens are available; positive results, while supportive, do not establish a definitive diagnosis. The histopathology of acute hypersensitivity pneumonitis is characterized by interstitial infiltrates of lymphocytes and plasma cells, with noncaseating granulomas in the interstitium and air spaces.

Table 9–20. Selected causes of hypersensitivity pneumonitis.

Disease	**Antigen**	**Source**
Farmer's lung	*Micropolyspora faeni*, *Thermoactinomyces vulgaris*	Moldy hay
"Humidifier" lung	Thermophilic actinomycetes	Contaminated humidifiers, heating systems, or air conditioners
Bird fancier's lung ("pigeon-breeder's disease")	Avian proteins	Bird serum and excreta
Bagassosis	*Thermoactinomyces*	Moldy sugar

	sacchari and *T vulgaris*	cane fiber (bagasse)
Sequoiosis	Graphium, Aureo basidium, and other fungi	Moldy redwood sawdust
Maple bark stripper's disease	*Cryptostroma (Coniosporium) corticale*	Rotting maple tree logs or bark
Mushroom picker's disease	Same as farmer's lung	Moldy compost
Suberosis	*Penicillium frequentans*	Moldy cork dust
Detergent worker's lung	*Bacillus subtilis* enzyme	Enzyme additives

Prompt diagnosis is essential since symptoms are usually reversible if the offending antigen is removed from the patient's environment early in the course of illness. Continued exposure may lead to progressive disease. A subacute hypersensitivity pneumonitis syndrome (15% of cases) is characterized by the insidious onset of chronic cough and slowly progressive dyspnea, anorexia, and weight loss. Chronic exposure leads to progressive respiratory insufficiency and the appearance of pulmonary fibrosis on chest imaging. Surgical lung biopsy may be necessary for the diagnosis of subacute and chronic hypersensitivity pneumonitis. Even with surgical lung biopsy, however, chronic hypersensitivity pneumonitis may be difficult to diagnose because histopathologic patterns overlap with several idiopathic interstitial pneumonias.

Treatment of acute hypersensitivity pneumonitis consists of identification of the offending agent and avoidance of further exposure. In severe acute or protracted cases, oral corticosteroids (prednisone, 0.5 mg/kg daily as a single morning dose for 2 weeks, tapered to nil over 4–6 weeks) may be given. Change in occupation is often unavoidable.

Ismail T et al. Extrinsic allergic alveolitis. Respirology. 2006 May;11(3):262–8. [PMID: 16635083]

Obstructive Airway Disorders

Occupational pulmonary diseases manifested as obstructive airway disorders include occupational asthma, industrial bronchitis, and byssinosis.

Occupational Asthma

It has been estimated that from 2% to 5% of all cases of asthma are related to occupation. Offending agents in the workplace are numerous; they include grain dust, wood dust, tobacco, pollens, enzymes, gum arabic, synthetic dyes, isocyanates (particularly toluene diisocyanate), rosin (soldering flux), inorganic chemicals (salts of nickel, platinum, and chromium), trimellitic anhydride, phthalic anhydride, formaldehyde, and various pharmaceutical agents. Diagnosis of occupational asthma depends on a high index of suspicion, an appropriate history, spirometric studies before and after exposure to the offending substance, and peak flow rate measurements in the workplace. Bronchial provocation testing may be helpful in some cases. Treatment consists of avoidance of further exposure to the offending agent and bronchodilators, but symptoms may persist for years after workplace exposure has been terminated.

Industrial Bronchitis

Industrial bronchitis is chronic bronchitis found in coal miners and others exposed to cotton, flax, or hemp dust. Chronic disability from industrial bronchitis is infrequent.

Byssinosis

Byssinosis is an asthma-like disorder in textile workers caused by inhalation of cotton dust. The pathogenesis is obscure. Chest tightness, cough, and dyspnea are characteristically worse on Mondays or the first day back at work, with symptoms subsiding later in the week. Repeated exposure leads to chronic bronchitis.

Toxic Lung Injury

Toxic lung injury from inhalation of irritant gases is discussed in the section on smoke inhalation. **Silo-filler's**

disease is acute toxic high-permeability pulmonary edema caused by inhalation of nitrogen dioxide encountered in recently filled silos. Bronchiolitis obliterans is a common late complication, which may be prevented by early treatment of the acute reaction with corticosteroids. Extensive exposure to silage gas may be fatal. Inhalation of the compound diacetyl, a constituent of butter-flavoring, has been linked to the development of bronchiolitis obliterans among microwave popcorn production workers.

Lung Cancer

Many industrial pulmonary carcinogens have been identified, including asbestos, radon gas, arsenic, iron, chromium, nickel, coal tar fumes, petroleum oil mists, isopropyl oil, mustard gas, and printing ink. Cigarette smoking acts as a cocarcinogen with asbestos and radon gas to cause bronchogenic carcinoma. Asbestos alone causes malignant mesothelioma. Almost all histologic types of lung cancer have been associated with these carcinogens. Chloromethyl methyl ether specifically causes small cell carcinoma of the lung.

Pleural Diseases

Occupational diseases of the pleura may result from exposure to asbestos (see above) or talc. Inhalation of talc causes pleural plaques that are similar to those caused by asbestos. Benign asbestos pleural effusion occurs in some asbestos workers and may cause chronic blunting of the costophrenic angle on chest radiograph.

Other Occupational Pulmonary Diseases

Occupational agents are also responsible for other pulmonary disorders. These include **berylliosis**, an acute or chronic pulmonary disorder related to exposure to beryllium, which is absorbed through the lungs or skin and widely disseminated throughout the body. Acute berylliosis is a toxic, ulcerative tracheobronchitis and chemical pneumonitis following intense and severe exposure to beryllium. Chronic berylliosis, a systemic disease closely resembling sarcoidosis, is more common. Chronic pulmonary beryllium disease is thought to be an alveolitis mediated by the proliferation of beryllium-specific helper-inducer T cells in the lung. Exposure to beryllium now occurs in machining and handling of beryllium products and alloys. Beryllium miners are not at risk for berylliosis. Beryllium is no longer used in fluorescent lamp production, which was a source of exposure before 1950.

Care Med. 2005 Aug 1;172(3):280–305. [PMID: 15860754]

Drug-Induced Lung Disease

Typical patterns of pulmonary response to drugs implicated in drug-induced respiratory disease are summarized in Table 9–21. Pulmonary injury due to drugs occurs as a result of allergic reactions, idiosyncratic reactions, overdose, or undesirable side effects. In most patients, the mechanism of pulmonary injury is unknown.

Table 9–21. Pulmonary manifestations of selected drug toxicities.

Asthma	**Pulmonary edema**
-Blockers	Noncardiogenic
Aspirin	Aspirin
Nonsteroidal anti-inflammatory drugs	Chlordiazepoxide
	Cocaine
Histamine	Ethchlorvynol
Methacholine	Heroin
Acetylcysteine	Cardiogenic
Aerosolized pentamidine	-Blockers
Any nebulized medication	**Pleural effusion**

Chronic cough	Bromocriptine
Angiotensin-converting enzyme inhibitors	Nitrofurantoin
Pulmonary infiltration	Any drug inducing systemic lupus erythematosus
Without eosinophilia	Methysergide
Amitriptyline	Chemotherapeutic agents
Azathioprine	**Mediastinal widening**
Amiodarone	Phenytoin
With eosinophilia	Corticosteroids
Sulfonamides	Methotrexate
L-Tryptophan	**Respiratory failure**
Nitrofurantoin	Neuromuscular blockade
Penicillin	Aminoglycosides
Methotrexate	Succinylcholine
Crack cocaine	Gallamine
Drug-induced systemic lupus erythematosus	Dimethyltubocurarine (metocurine)
Hydralazine	Central nervous system depression
Procainamide	Sedatives
Isoniazid	Hypnotics
Chlorpromazine	Opioids

Phenytoin	Alcohol
Interstitial pneumonitis/fibrosis	Tricyclic antidepressants
Nitrofurantoin	Oxygen
Bleomycin	
Busulfan	
Cyclophosphamide	
Methysergide	
Phenytoin	

Precise diagnosis of drug-induced pulmonary disease is often difficult, because results of routine laboratory studies are not helpful and radiographic findings are not specific. A high index of suspicion and a thorough medical history of drug usage are critical to establishing the diagnosis of drug-induced lung disease. The clinical response to cessation of the suspected offending agent is also helpful. Acute episodes of drug-induced pulmonary disease usually disappear 24–48 hours after the drug has been discontinued, but chronic syndromes may take longer to resolve. Challenge tests to confirm the diagnosis are risky and rarely performed.

Treatment of drug-induced lung disease consists of discontinuing the offending agent immediately and managing the pulmonary symptoms appropriately.

Inhalation of crack cocaine may cause a spectrum of acute pulmonary syndromes, including pulmonary infiltration with eosinophilia, pneumothorax and pneumomediastinum, bronchiolitis obliterans, and acute respiratory failure associated with diffuse alveolar damage and alveolar hemorrhage. Corticosteroids have been used with variable success to treat alveolar hemorrhage.

Huggins JT et al. Drug-induced pleural disease. Clin Chest Med. 2004 Mar;25(1):141–53. [PMID: 15062606]

Radiation Lung Injury

The lung is an exquisitely radiosensitive organ that can be damaged by external beam radiation therapy. The degree of pulmonary injury is determined by the volume of lung irradiated, the dose and rate of exposure, and potentiating factors (eg, concurrent chemotherapy, previous radiation therapy in the same area, and simultaneous withdrawal of corticosteroid therapy). Symptomatic radiation lung injury occurs in about 10% of patients treated for carcinoma of the breast, 5–15% of patients treated for carcinoma of the lung, and 5–35% of patients treated for lymphoma. Two phases of the pulmonary response to radiation are apparent: an acute phase (radiation pneumonitis) and a chronic phase (radiation fibrosis).

Radiation Pneumonitis

Radiation pneumonitis usually occurs 2–3 months (range 1–6 months) after completion of radiotherapy and is characterized by insidious onset of dyspnea, intractable dry cough, chest fullness or pain, weakness, and fever. The pathogenesis of acute radiation pneumonitis is unknown, but there is speculation that hypersensitivity mechanisms are involved. The dominant histopathologic findings are a lymphocytic interstitial pneumonitis progressing to an exudative alveolitis. Inspiratory crackles may be heard in the involved area. In severe disease, respiratory distress and cyanosis occur that are characteristic of ARDS. An increased white blood cell count and elevated sedimentation rate are common. Pulmonary function studies reveal reduced lung volumes, reduced lung compliance, hypoxemia, reduced diffusing capacity, and reduced maximum voluntary ventilation. Chest radiography, which correlates poorly with the presence of symptoms, usually demonstrates an alveolar or nodular infiltrate limited to the irradiated area. Air bronchograms are often observed. Sharp borders of the infiltrate may help distinguish radiation pneumonitis from other conditions such as infectious pneumonia, lymphangitic spread of carcinoma, and recurrent tumor. No specific therapy is proved to be effective in radiation pneumonitis, but prednisone (1 mg/kg/d orally) is commonly given immediately for about 1 week. The dose is then reduced and maintained at 20–40 mg/d for several weeks, then slowly tapered. Radiation pneumonitis may improve in 2–3 weeks following onset of symptoms as the exudative phase resolves. Acute respiratory failure, if present, is treated supportively. Death from ARDS is unusual in radiation pneumonitis.

Pulmonary Radiation Fibrosis

Pulmonary radiation fibrosis occurs in nearly all patients who receive a full course of radiation therapy for cancer of the lung or breast. Patients who experience radiation pneumonitis develop pulmonary fibrosis after an intervening period (6–12 months) of well-being. Most patients are asymptomatic, though slowly progressive dyspnea may occur. Radiation fibrosis may occur with or without antecedent radiation pneumonitis. Cor pulmonale and chronic respiratory failure are rare. Radiographic findings include obliteration of normal lung markings, dense interstitial and pleural fibrosis, reduced lung volumes, tenting of the diaphragm, and sharp delineation of the irradiated area. No specific therapy is proven effective, and corticosteroids have no value.

Other Complications of Radiation Therapy

Other complications of radiation therapy directed to the thorax include pericardial effusion, constrictive pericarditis, tracheoesophageal fistula, esophageal candidiasis, radiation dermatitis, and rib fractures. Small pleural effusions, radiation pneumonitis outside the irradiated area, spontaneous pneumothorax, and complete obstruction of central airways are unusual occurrences.

Camus P et al. Interstitial lung disease induced by drugs and radiation. Respiration. 2004 Jul–Aug;71(4):301–26. [PMID: 15316202]

Pleuritis

Pain due to acute pleural inflammation is caused by irritation of the parietal pleura. Such pain is localized, sharp, and fleeting; it is made worse by coughing, sneezing, deep breathing, or movement. When the central portion of the diaphragmatic parietal pleura is irritated, pain may be referred to the ipsilateral shoulder. There are numerous causes of pleuritis. The setting in which pleuritic pain develops helps narrow the differential diagnosis. In young, otherwise healthy individuals, pleuritis is usually caused by viral respiratory infections or pneumonia. The presence of pleural effusion, pleural thickening, or air in the pleural space requires further diagnostic and therapeutic measures. Simple rib fracture may cause severe pleurisy.

Treatment of pleuritis consists of treating the underlying disease. Analgesics and anti-inflammatory drugs (eg, indomethacin, 25 mg orally two or three times daily) are often helpful for pain relief. Codeine (30–60 mg orally every 8 hours) may be used to control cough associated with pleuritic chest pain if retention of airway secretions is not a likely complication. Intercostal nerve blocks are sometimes helpful but the benefit is usually transient.

Pleural Effusion

Essentials of Diagnosis

- May be asymptomatic; chest pain frequently seen in the setting of pleuritis, trauma, or infection; dyspnea is common with large effusions.
- Dullness to percussion and decreased breath sounds over the effusion.
- Radiographic evidence of pleural effusion.
- Diagnostic findings on thoracentesis.

General Considerations

There is constant movement of fluid from parietal pleural capillaries into the pleural space at a rate of 0.01 mL/kg body weight/h. Absorption of pleural fluid occurs through parietal pleural lymphatics. The resultant homeostasis leaves 5–15 mL of fluid in the normal pleural space. A pleural effusion is an abnormal accumulation of fluid in the pleural space. Pleural effusions may be classified by differential diagnosis (Table 9–22) or by underlying pathophysiology. Five pathophysiologic processes account for most pleural effusions: increased production of fluid in the setting of normal capillaries due to increased hydrostatic or decreased oncotic pressures (transudates); increased production of fluid due to abnormal capillary permeability (exudates); decreased lymphatic clearance of fluid from the pleural space (exudates); infection in the pleural space (empyema); and bleeding into the pleural space (hemothorax).

Table 9–22. Causes of pleural fluid transudates and exudates.

Transudates	**Exudates**
Congestive heart failure (> 90% of cases)	Pneumonia (parapneumonic effusion)
Cirrhosis with ascites	Cancer
Nephrotic syndrome	Pulmonary embolism
Peritoneal dialysis	Bacterial infection
Myxedema	Tuberculosis
Acute atelectasis	Connective tissue disease
Constrictive pericarditis	Viral infection

Superior vena cava obstruction	Fungal infection
Pulmonary embolism	Rickettsial infection
	Parasitic infection
	Asbestos
	Meigs syndrome
	Pancreatic disease
	Uremia
	Chronic atelectasis
	Trapped lung
	Chylothorax
	Sarcoidosis
	Drug reaction
	Post-myocardial infarction syndrome

Diagnostic thoracentesis should be performed whenever there is a new pleural effusion and no clinically apparent cause (see illustration); (see illustration); (see illustration). Observation is appropriate in some situations (eg, symmetric bilateral pleural effusions in the setting of congestive heart failure), but an atypical presentation or failure of an effusion to resolve as expected warrants thoracentesis. Sampling allows visualization of the fluid in addition to chemical and microbiologic analyses to identify the pathophysiologic processes listed above. A definitive diagnosis is made through positive cytology or identification of a specific causative organism in approximately 25% of cases. In another 50–60% of patients, identification of relevant pathophysiology in the appropriate clinical setting greatly narrows the differential diagnosis and leads to a presumptive diagnosis.

Clinical Findings

Symptoms and Signs

Patients with pleural effusions most often report dyspnea, cough, or respirophasic chest pain. Symptoms are more common in patients with existing cardiopulmonary disease. Small pleural effusions are less likely to be symptomatic than larger effusions. Physical findings are usually absent in small effusions. Larger effusions may present with dullness to percussion and diminished or absent breath sounds over the effusion. Compressive atelectasis may cause bronchial breath sounds and egophony just above the effusion. A massive effusion with increased intrapleural pressure may cause contralateral shift of the trachea and bulging of the intercostal spaces. A pleural friction rub indicates infarction or pleuritis .

Audio
Lung sound: pleural friction rub. Note that it is heard in both inspiration and expiration and that it has both continuous and discontinuous portions. (Reproduced, with permission, from Raymond L.H. Murphy, Jr., MD: *A Simplified Introduction to Lung Sounds* [audio tape], 1977.)

Laboratory Findings

The gross appearance of pleural fluid helps identify several types of pleural effusion. Grossly purulent fluid signifies empyema, an infection of the pleural space. Milky white pleural fluid should be centrifuged. A clear supernatant above a pellet of white cells indicates empyema, whereas a persistently turbid supernatant suggests a chylous effusion. Analysis of this supernatant reveals chylomicrons and a high triglyceride level (> 100 mg/dL), often from traumatic disruption of the thoracic duct. Hemorrhagic pleural effusion is a mixture of blood and pleural fluid. Ten thousand red cells per milliliter create blood-tinged pleural fluid; 100,000/mL create grossly bloody pleural fluid. Hemothorax is the presence of gross blood in the pleural space, usually following chest trauma or instrumentation. It is defined as a ratio of pleural fluid hematocrit to peripheral blood hematocrit > 0.5.

Pleural fluid samples should be sent for measurement of protein, glucose, and LD in addition to total and differential white blood cell counts. Chemistry determinations are used to classify effusions as transudates or exudates. This classification is important because the differential diagnosis for each entity is vastly different (Table 9–22). A pleural exudate is an effusion that has *one or more* of the following laboratory features: (1) ratio of pleural fluid protein to serum protein > 0.5; (2) ratio of pleural fluid LD to serum LD > 0.6; (3) pleural fluid LD greater than two-thirds the upper limit of normal serum LD.

Transudates have none of these features. Transudates occur in the setting of normal capillary integrity and suggest the *absence* of local pleural disease. Distinguishing laboratory findings include a glucose equal to serum glucose, pH between 7.40 and 7.55, and fewer than 1000 white blood cells/mcL with a predominance of mononuclear cells. Causes include increased hydrostatic pressure (congestive heart failure accounts for 90% of transudates), decreased oncotic pressure (hypoalbuminemia, cirrhosis), and greater negative pleural pressure (acute atelectasis). Exudates form as a result of pleural disease associated with increased capillary permeability or reduced lymphatic drainage. Bacterial pneumonia and cancer are the most common causes of exudative effusion, but there are many other causes with characteristic laboratory findings. These findings are summarized in Table 9–23.

Table 9–23. Characteristics of important exudative pleural effusions.

Etiology or Type of Effusion	**Gross Appearance**	**White Blood Cell Count (cells/ mcL)**	**Red Blood Cell Count (cells/ mcL)**	**Glucose**	**Comments**
Malignant effusion	Turbid to bloody; occasionally serous	1000 to < 100,000 M	100 to several hundred thousand	Equal to serum levels; < 60 mg/dL	Eosinophilia uncommon; positive results on

				in 15% of cases	cytologic examination
Uncomplicated parapneumonic effusion	Clear to turbid	5000–25,000 P	< 5000	Equal to serum levels	Tube thoracostomy unnecessary
Empyema	Turbid to purulent	25,000–100,000 P	< 5000	Less than serum levels; often very low	Drainage necessary; putrid odor suggests anaerobic infection
Tuberculosis	Serous to serosanguineous	5000–10,000 M	< 10,000	Equal to serum levels; occasionally < 60 mg/dL	Protein > 4.0 g/dL and may exceed 5 g/dL; eosinophils (> 10%) or mesothelial cells (> 5%) make

					diagnosis unlikely
Rheumatoid effusion	Turbid; greenish yellow	1000–20,000 M or P	< 1000	< 40 mg/dL	Secondary empyema common; high LD, low complement, high rheumatoid factor, cholesterol crystals are characteristic
Pulmonary infarction	Serous to grossly bloody	1000–50,000 M or P	100 to > 100,000	Equal to serum levels	Variable findings; no pathognomonic features
Esophageal rupture	Turbid to purulent; red-brown	< 5000 to > 50,000	1000–10,000	Usually low	High amylase level

		P			(salivary origin); pneumothorax in 25% of cases; effusion usually on left side; pH < 6.0 strongly suggests diagnosis
Pancreatitis	Turbid to serosanguineous	1000–50,000 P	1000–10,000	Equal to serum levels	Usually left-sided; high amylase level

LD, lactate dehydrogenase; M, mononuclear cell predominance; P, polymorphonuclear leukocyte predominance.

Pleural fluid pH is useful in the assessment of parapneumonic effusions. A pH below 7.30 suggests the need for drainage of the pleural space. An elevated amylase level in pleural fluid suggests pancreatitis, pancreatic pseudocyst, adenocarcinoma of the lung or pancreas, or esophageal rupture.

Thoracentesis with culture and pleural biopsy is indicated in suspected tuberculous pleural effusion. Pleural fluid culture is 44% sensitive, and the combination of closed pleural biopsy with culture and histologic examination for granulomas is 70–90% sensitive for the diagnosis of pleural tuberculosis.

Pleural fluid specimens should be sent for cytologic examination in all cases of exudative effusions in patients suspected of harboring an underlying malignancy. The diagnostic yield depends on the nature and extent of the underlying malignancy. Sensitivity is between 50% and 65%. A negative cytologic examination in a patient with a high prior probability of malignancy should be followed by one repeat thoracentesis. If that examination is negative, thoracoscopy (by a pulmonologist or by VATS) is preferred to closed pleural biopsy. The sensitivity of thoracoscopy is 92–96%.

Imaging

The lung is less dense than water and floats on pleural fluid that accumulates in dependent regions (see x-ray). Subpulmonary fluid may appear as lateral displacement of the apex of the diaphragm with an abrupt slope to the costophrenic sulcus or a greater than 2-cm separation between the gastric air bubble and the lung. On a standard upright chest radiograph, approximately 75–100 mL of pleural fluid must accumulate in the posterior costophrenic sulcus to be visible on the lateral view, and 175–200 mL must be present in the lateral costophrenic sulcus to be visible on the frontal view. Chest CT scans may identify as little as 10 mL of fluid. At least 1 cm of fluid on the decubitus view is necessary to permit blind thoracentesis. Ultrasonography is useful to guide thoracentesis in the setting of smaller effusions.

Fig.

A: Pleural effusion. The elevation of the left hemidiaphragm may be caused by a pleural effusion at the left base. The appropriate way to determine the nature of this abnormality is to obtain a left lateral decubitus film (see ***B***). ***B:*** The lateral decubitus film in the same patient demonstrates a very large left pleural effusion. In looking at the upright view of the chest, it is clear that the effusion was beneath the left lung and therefore had a contour simulating that of an elevated left hemidiaphragm. ***C:*** The opposite lateral decubitus film shows that a small effusion was also present on the right side. (Courtesy of H Goldberg.)

Pleural fluid may become trapped (loculated) by pleural adhesions, thereby forming unusual collections along the lateral chest wall or within lung fissures (see x-ray). Round or oval fluid collections in fissures that resemble intraparenchymal masses are called pseudotumors. Massive pleural effusion causing opacification of an entire hemithorax is most commonly caused by cancer but may be seen in tuberculosis and other diseases.

Fig.

A: Pleural effusion. The lateral border of the right hemithorax shows evidence of a loculated pleural effusion. To determine whether this effusion is indeed loculated, a decubitus film must be obtained. ***B:*** The decubitus view demonstrates that the fluid is not loculated. (Courtesy of H Goldberg.)

Treatment

Transudative Pleural Effusion

Transudative pleural effusions characteristically occur in the absence of pleural disease. Treatment is directed at the underlying condition. Therapeutic thoracentesis for severe dyspnea typically offers only transient benefit. Pleurodesis and tube thoracostomy are rarely indicated.

Malignant Pleural Effusion

Approximately 15% of patients dying of cancer are reported to have malignant pleural effusions. Almost any form of cancer may cause effusions, but the most common causes are lung cancer (one-third of cases) and breast cancer. In 5–10% of malignant pleural effusions, no primary tumor is identified.

Between 40% and 80% of exudative pleural effusions are malignant, while over 90% of malignant pleural effusions are exudative. The most common mechanisms contributing to the formation of malignant effusions include direct tumor involvement of the pleura, local inflammation in response to tumor spread, and impairment or disruption of lymphatics. The term "paramalignant pleural effusion" refers to an effusion in a patient with cancer when repeated attempts to identify tumor cells in the pleura or pleural fluid are nondiagnostic but when there is a presumptive relation to the underlying malignancy. For example, superior vena cava syndrome with elevated systemic venous pressures causing a transudative effusion would be "paramalignant."

Most patients with malignant effusions have advanced disease and multiple symptoms. Dyspnea occurs in over half of patients with malignant pleural effusions. The cause of dyspnea is probably related to mechanical distortion of the lung and chest wall. Hypoxemia from intrapulmonary shunting and / mismatching is common and may be severe. Treatment may be systemic, with therapy for the underlying malignancy; or local, to address specific symptoms related to the effusion itself. Local treatment usually involves drainage through repeated thoracentesis or placement of a chest tube. Pleurodesis is a procedure by which an irritant is placed into the pleural space following chest tube drainage and lung reexpansion. The goal is to form fibrous adhesions between the visceral and parietal pleura, resulting in obliteration of the pleural space to prevent or significantly reduce reaccumulation of pleural fluid. Multiple agents have been used for pleurodesis, but the two in most common use are doxycycline (500 mg in 50–100 mL saline) and sterile, asbestos-free talc (by poudrage at thoracoscopy using 5 g or instillation of talc slurry through a chest tube using 4–5 g in 50 mL saline). Doxycycline and talc are associated with a 70–75% and a 90% success rate, respectively. Major side effects are pain and fever, which appear to be less common with talc. Pain associated with pleurodesis can be extreme. Patients should be premedicated with an anxiolytic-amnestic agent in addition to opioid analgesics.

Alternative strategies include an indwelling pleural catheter (eg, Pleurex) to facilitate home drainage. These catheters provide suitable ambulatory patients symptom relief while avoiding hospitalization, with approximately a 40% rate of spontaneous pleurodesis.

Parapneumonic Pleural Effusion

Parapneumonic pleural effusions are exudates that accompany approximately 40% of bacterial pneumonias. They are divided into three categories: simple or uncomplicated, complicated, and empyema. Uncomplicated parapneumonic effusions are free-flowing sterile exudates of modest size that resolve quickly with antibiotic treatment of pneumonia. They do not need drainage. Empyema is gross infection of the pleural space indicated by positive Gram stain or culture. Empyema should always be drained by tube thoracostomy to facilitate clearance of infection and to reduce the probability of fibrous encasement of the lung, causing permanent pulmonary impairment.

Complicated parapneumonic effusions present the most difficult management decisions. They tend to be larger than simple parapneumonic effusions and to show more evidence of inflammatory stimuli such as low glucose level, low pH, or evidence of loculation. Inflammation probably reflects ongoing bacterial invasion of the pleural space despite rare positive bacterial cultures. The morbidity associated with complicated effusions is due to their tendency to form a fibropurulent pleural "peel," trapping otherwise functional lung and leading to permanent impairment. Tube thoracostomy is indicated when pleural fluid glucose is < 60 mg/dL or the pH is < 7.2. These thresholds have not been prospectively validated and should not be interpreted strictly. The clinician should consider drainage of a complicated effusion if the pleural fluid pH is between 7.2 and 7.3 or the LD is > 1000 units/mL. Pleural fluid cell count and protein have little diagnostic value in this setting.

Tube thoracostomy drainage of empyema or parapneumonic effusions is frequently complicated by loculation that prevents adequate drainage. Intrapleural injection of fibrinolytic agents (streptokinase, 250,000 units, or urokinase, 100,000 units, in 50–100 mL of normal saline once or twice daily) is often used to improve drainage, although data are mixed as to whether this intervention improves outcomes.

Hemothorax

A small-volume hemothorax that is stable or improving on chest radiographs may be managed by close observation. In all other cases, hemothorax is treated by immediate insertion of a large-bore thoracostomy tube to (1) drain existing blood and clot, (2) quantify the amount of bleeding, (3) reduce the risk of fibrothorax, and (4) permit apposition of the pleural surfaces in an attempt to reduce hemorrhage. Thoracotomy may be indicated to control hemorrhage, remove clot, and treat complications such as bronchopleural fistula formation.

Spontaneous Pneumothorax

Essentials of Diagnosis

- Acute onset of unilateral chest pain and dyspnea.
- Minimal physical findings in mild cases; unilateral chest expansion, decreased tactile fremitus, hyperresonance, diminished breath sounds, mediastinal shift, cyanosis and hypotension in tension pneumothorax.
- Presence of pleural air on chest radiograph.

General Considerations

Pneumothorax, or accumulation of air in the pleural space, is classified as spontaneous (primary or secondary) or traumatic. Primary spontaneous pneumothorax occurs in the absence of an underlying lung disease, whereas secondary spontaneous pneumothorax is a complication of preexisting pulmonary disease. Traumatic pneumothorax results from penetrating or blunt trauma. Iatrogenic pneumothorax may follow procedures such as thoracentesis, pleural biopsy, subclavian or internal jugular vein catheter placement, percutaneous lung biopsy, bronchoscopy with transbronchial biopsy, and positive-pressure mechanical ventilation. Tension pneumothorax usually occurs in the setting of penetrating trauma, lung infection, cardiopulmonary resuscitation, or positive-pressure mechanical ventilation. In tension pneumothorax, the pressure of air in the pleural space exceeds ambient pressure throughout the respiratory cycle. A check-valve mechanism allows air to enter the pleural space on inspiration and prevents egress of air on expiration.

Primary pneumothorax affects mainly tall, thin boys and men between the ages of 10 and 30 years. It is thought to occur from rupture of subpleural apical blebs in response to high negative intrapleural pressures. Family history and cigarette smoking may also be important factors.

Secondary pneumothorax occurs as a complication of COPD, asthma, cystic fibrosis, tuberculosis, *Pneumocystis* pneumonia, menstruation (catamenial pneumothorax), and a wide variety of interstitial lung diseases including sarcoidosis, lymphangioleiomyomatosis, Langerhans cell histiocytosis, and tuberous sclerosis. Aerosolized pentamidine and a prior history of *Pneumocystis* pneumonia are considered risk factors for the development of pneumothorax. One-half of patients with pneumothorax in the setting of recurrent *Pneumocystis* pneumonia will develop pneumothorax on the contralateral side. The mortality rate of pneumothorax in *Pneumocystis* pneumonia is high.

Clinical Findings

Symptoms and Signs

Chest pain ranging from minimal to severe on the affected side and dyspnea occur in nearly all patients. Symptoms usually begin during rest and usually resolve within 24 hours even if the pneumothorax persists. Alternatively, pneumothorax may present with life-threatening respiratory failure if underlying COPD or asthma is present.

If pneumothorax is small (less than 15% of a hemithorax), physical findings, other than mild tachycardia, are unimpressive. If pneumothorax is large, diminished breath sounds, decreased tactile fremitus, and decreased movement of the chest are often noted. Tension pneumothorax should be suspected in the presence of marked tachycardia, hypotension, and mediastinal or tracheal shift.

Laboratory Findings

Arterial blood gas analysis is often unnecessary but reveals hypoxemia and acute respiratory alkalosis in most patients. Left-sided primary pneumothorax may produce QRS axis and precordial T wave changes on the ECG that may be misinterpreted as acute myocardial infarction.

Imaging

Demonstration of a visceral pleural line on chest radiograph is diagnostic and may only be seen on an expiratory film (see x-ray). A few patients have secondary pleural effusion that demonstrates a characteristic air-fluid level on chest radiography. In supine patients, pneumothorax on a conventional chest radiograph may appear as an abnormally radiolucent costophrenic sulcus (the "deep sulcus" sign) (see x-ray). In patients with tension pneumothorax, chest radiographs show a large amount of air in the affected hemithorax and contralateral shift of the mediastinum (see x-ray).

Fig.

Early tension pneumothorax. The right lung is collapsed, and no vessels can be seen traversing the right hemithorax. The mediastinum is shifted slightly to the left. These are features of a large pneumothorax, with some tension component causing a shift of the mediastinum. (Courtesy of H Goldberg.)

Differential Diagnosis

If the patient is a young, tall, thin, cigarette-smoking man, the diagnosis of primary spontaneous pneumothorax is usually obvious and can be confirmed by chest radiograph. In secondary pneumothorax, it is sometimes difficult to distinguish loculated pneumothorax from an emphysematous bleb. Occasionally, pneumothorax may mimic myocardial infarction, pulmonary embolization, or pneumonia.

Complications

Tension pneumothorax may be life-threatening. Pneumomediastinum and subcutaneous emphysema may occur as complications of spontaneous pneumothorax. If pneumomediastinum is detected, rupture of the esophagus or a bronchus should be considered (see x-ray).

Fig.

A: Pneumomediastinum secondary to esophageal perforation (posteroanterior chest radiograph). ***B:*** Pneumomediastinum (lateral chest radiograph). (Courtesy of H Goldberg.)

Treatment

Treatment depends on the severity of pneumothorax and the nature of the underlying disease. In a reliable patient with a small (< 15% of a hemithorax), stable spontaneous primary pneumothorax, observation alone may be appropriate. Many small pneumothoraces resolve spontaneously as air is absorbed from the pleural space; supplemental oxygen therapy may increase the rate of reabsorption. Simple aspiration drainage of pleural air with a small-bore catheter (eg, 16 gauge angiocatheter or larger drainage catheter) can be performed for spontaneous primary pneumothoraces that are large or progressive. Placement of a small-bore chest tube (7F to 14F) attached to a one-way Heimlich valve provides protection against development of tension pneumothorax and may permit observation from home. The patient should be treated symptomatically for cough and chest pain, and followed with serial chest radiographs every 24 hours.

Patients with secondary pneumothorax, large pneumothorax, tension pneumothorax, or severe symptoms or those who have a pneumothorax on mechanical ventilation should undergo chest tube placement (tube thoracostomy). The chest tube is placed under water-seal drainage, and suction is applied until the lung expands. The chest tube can be removed after the air leak subsides.

All patients who smoke should be advised to discontinue smoking and warned that the risk of recurrence is 50%. Future exposure to high altitudes, flying in unpressurized aircraft, and scuba diving should be avoided.

Indications for thoracoscopy or open thoracotomy include recurrences of spontaneous pneumothorax, any occurrence of bilateral pneumothorax, and failure of tube thoracostomy for the first episode (failure of lung to reexpand or persistent air leak). Surgery permits resection of blebs responsible for the pneumothorax and pleurodesis by mechanical abrasion and insufflation of talc.

Management of pneumothorax in patients with *Pneumocystis* pneumonia is challenging because of a tendency toward recurrence, and there is no consensus on the best approach. Use of a small chest tube attached to a Heimlich valve has been proposed to allow the patient to leave the hospital. Some clinicians favor its insertion early in the course.

Prognosis

An average of 30% of patients with spontaneous pneumothorax experience recurrence of the disorder after either observation or tube thoracostomy for the first episode. Recurrence after surgical therapy is less frequent. Following successful therapy, there are no long-term complications.

Disorders of Control of Ventilation: Introduction

The principal influences on ventilatory control are arterial PCO_2, pH, PO_2, and brainstem tissue pH. These variables are monitored by peripheral and central chemoreceptors. Under normal conditions, the ventilatory control system maintains arterial pH and PCO_2 within narrow limits; arterial PO_2 is more loosely controlled.

Abnormal control of ventilation can be seen with a variety of conditions ranging from rare disorders such as Ondine curse, neuromuscular disorders, myxedema, starvation, and carotid body resection to more common disorders such as asthma, COPD, obesity, congestive heart failure, and sleep-related breathing disorders. A few of these disorders will be discussed in this section.

Annane D et al. Nocturnal mechanical ventilation for chronic hypoventilation in patients with neuromuscular and chest wall disorders. Cochrane Database Syst Rev. 2007 Oct 17;(4):CD001941. [PMID: 17943762]

Primary Alveolar Hypoventilation

Primary alveolar hypoventilation ("Ondine curse") is a rare syndrome of unknown cause characterized by inadequate alveolar ventilation despite normal neurologic function and normal airways, lungs, chest wall, and ventilatory muscles. Hypoventilation is even more marked during sleep. Individuals with this disorder are usually nonobese males in their third or fourth decades who have lethargy, headache, and somnolence. Dyspnea is absent. Physical examination may reveal cyanosis and evidence of pulmonary hypertension and cor pulmonale. Hypoxemia and hypercapnia are present and improve with voluntary hyperventilation. Erythrocytosis is common. Treatment with ventilatory stimulants is usually unrewarding. Augmentation of ventilation by mechanical methods (phrenic nerve stimulation, rocking bed, mechanical ventilators) has been helpful to some patients. Adequate oxygenation should be maintained with supplemental oxygen, but nocturnal oxygen therapy should be prescribed only if diagnostic nocturnal polysomnography has demonstrated its efficacy and safety. Primary alveolar hypoventilation resembles—but should be distinguished from—**central alveolar hypoventilation**, in which impaired ventilatory drive with chronic respiratory acidemia and hypoxemia follows an insult to the brainstem (eg, bulbar poliomyelitis, infarction, meningitis, encephalitis, trauma).

Obesity-Hypoventilation Syndrome (Pickwickian Syndrome)

In obesity-hypoventilation syndrome, alveolar hypoventilation appears to result from a combination of blunted ventilatory drive and increased mechanical load imposed upon the chest by obesity. Voluntary hyperventilation returns the PCO_2 and the PO_2 toward normal values, a correction not seen in lung diseases causing chronic respiratory failure such as COPD. Most patients with obesity-hypoventilation syndrome also suffer from obstructive sleep apnea (see Sleep-Related Breathing Disorders), which must be treated aggressively if identified as a comorbid disorder. Therapy of obesity-hypoventilation syndrome consists mainly of weight loss, which improves hypercapnia and hypoxemia as well as the ventilatory responses to hypoxia and hypercapnia. NPPV is helpful in some patients. Respiratory stimulants may be helpful and include theophylline, acetazolamide, and medroxyprogesterone acetate, 10–20 mg every 8 hours orally. Improvement in hypoxemia, hypercapnia, erythrocytosis, and cor pulmonale are goals of therapy.

Mokhlesi B et al. Assessment and management of patients with obesity hypoventilation syndrome. Proc Am Thorac Soc. 2008 Feb 15;5(2):218–25. [PMID: 18250215]

Hyperventilation Syndromes

Hyperventilation is an increase in alveolar ventilation that leads to hypocapnia. It may be caused by a variety of conditions, such as pregnancy, hypoxemia, obstructive and infiltrative lung diseases, sepsis, hepatic dysfunction, fever, and pain. The term “central neurogenic hyperventilation” denotes a monotonous, sustained pattern of rapid and deep breathing seen in comatose patients with brainstem injury of multiple causes. Functional hyperventilation may be acute or chronic. **Acute** hyperventilation presents with hyperpnea, paresthesias, carpopedal spasm, tetany, and anxiety. **Chronic** hyperventilation may present with various nonspecific symptoms, including fatigue, dyspnea, anxiety, palpitations, and dizziness. The diagnosis of chronic hyperventilation syndrome is established if symptoms are reproduced during voluntary hyperventilation. Once organic causes of hyperventilation have been excluded, treatment of acute hyperventilation consists of rebreathing expired gas from a paper bag held over the face in order to decrease respiratory alkalemia and its associated symptoms. Anxiolytic drugs may also be useful.

Foster GT et al. Respiratory alkalosis. Respir Care. 2001 Apr;46(4):384–91. [PMID: 11262557]

Laffey JG et al. Hypocapnia. N Engl J Med. 2002 Jul 4;347(1):43–53. [PMID: 12097540]

Sleep-Related Breathing Disorders

Abnormal ventilation during sleep is manifested by apnea (breath cessation for at least 10 seconds) or hypopnea (decrement in airflow with drop in hemoglobin saturation of at least 4%). Episodes of apnea are **central** if ventilatory effort is absent for the duration of the apneic episode, **obstructive** if ventilatory effort persists throughout the apneic episode but no airflow occurs because of transient obstruction of the upper airway, and **mixed** if absent ventilatory effort precedes upper airway obstruction during the apneic episode. Pure central sleep apnea is uncommon; it may be an isolated finding or may occur in patients with primary alveolar hypoventilation or with lesions of the brainstem. Obstructive and mixed sleep apneas are more common and may be associated with life-threatening cardiac arrhythmias, severe hypoxemia during sleep, daytime somnolence, pulmonary hypertension, cor pulmonale, systemic hypertension, and secondary erythrocytosis.

Definitive diagnostic evaluation for suspected sleep apnea should include otorhinolaryngologic examination and overnight polysomnography (the monitoring of multiple physiologic factors during sleep). Electroencephalography, electro-oculography, electromyography, electrocardiography, pulse oximetry, and measurement of respiratory effort and airflow are performed in a complete evaluation. Screening may be performed using home nocturnal pulse oximetry, which when normal has a high negative predictive value in ruling out significant sleep apnea.

Obstructive Sleep Apnea

Essentials of Diagnosis

- Daytime somnolence or fatigue.
- A history of loud snoring with witnessed apneic events.
- Overnight polysomnography demonstrating apneic

episodes with hypoxemia.

General Considerations

Upper airway obstruction during sleep occurs when loss of normal pharyngeal muscle tone allows the pharynx to collapse passively during inspiration. Patients with anatomically narrowed upper airways (eg, micrognathia, macroglossia, obesity, tonsillar hypertrophy) are predisposed to the development of obstructive sleep apnea. Ingestion of alcohol or sedatives before sleeping or nasal obstruction of any type, including the common cold, may precipitate or worsen the condition. Hypothyroidism and cigarette smoking are additional risk factors for obstructive sleep apnea. Before making the diagnosis of obstructive sleep apnea, a drug history should be obtained and a seizure disorder, narcolepsy, and depression should be excluded.

Clinical Findings

Symptoms and Signs

Most patients with obstructive or mixed sleep apnea are obese middle-aged men. Systemic hypertension is common. Patients may complain of excessive daytime somnolence, morning sluggishness and headaches, daytime fatigue, cognitive impairment, recent weight gain, and impotence. Bed partners usually report loud cyclical snoring, breath cessation, witnessed apneas, restlessness, and thrashing movements of the extremities during sleep. Personality changes, poor judgment, work-related problems, depression, and intellectual deterioration (memory impairment, inability to concentrate) may also be observed.

Physical examination may be normal or may reveal systemic and pulmonary hypertension with cor pulmonale. The patient may appear sleepy or even fall asleep during the evaluation. The oropharynx is frequently found to be narrowed by excessive soft tissue folds, large tonsils, pendulous uvula, or prominent tongue. Nasal obstruction by a deviated nasal septum, poor nasal airflow, and a nasal twang to the speech may be observed. A "bull neck" appearance is common.

Laboratory Findings

Erythrocytosis is common. A hemoglobin level and thyroid function tests should be obtained. Observation of the sleeping patient reveals loud snoring interrupted by episodes of increasingly strong ventilatory effort that fail to produce airflow. A loud snort often accompanies the first breath following an apneic episode. **Polysomnography** reveals apneic episodes lasting as long as 60 seconds. Oxygen saturation falls, often to very low levels. Bradydysrhythmias such as sinus bradycardia, sinus arrest, or atrioventricular block may occur. Tachydysrhythmias, including paroxysmal supraventricular tachycardia, atrial fibrillation, and ventricular tachycardia, may be seen once airflow is reestablished.

Treatment

Weight loss and strict avoidance of alcohol and hypnotic medications are the first steps in management. Weight loss may be curative, but most patients are unable to lose the 10–20% of body weight required. **Nasal continuous positive airway pressure (nasal CPAP)** at night is curative in many patients. Polysomnography is frequently necessary to determine the level of CPAP (usually 5–15 cm H_2O) necessary to abolish obstructive apneas. Unfortunately, only about 75% of patients continue to use nasal CPAP after 1 year. Pharmacologic therapy for obstructive sleep apnea is disappointing. Supplemental oxygen may lessen the severity of nocturnal desaturation but may also lengthen apneas; it should not be routinely prescribed. Polysomnography is necessary to assess the effects of oxygen therapy. Mechanical devices inserted into the mouth at bedtime to hold the jaw forward and prevent pharyngeal occlusion have modest effectiveness in relieving apnea; however, patient compliance is not optimal.

Uvulopalatopharyngoplasty (UPPP), a procedure consisting of resection of pharyngeal soft tissue and amputation of approximately 15 mm of the free edge of the soft palate and uvula, is helpful in approximately 50% of selected patients. It is more effective in eliminating snoring than apneic episodes. UPPP may now be performed on an outpatient basis with a laser. **Nasal septoplasty** is performed if gross anatomic nasal septal deformity is present. **Tracheotomy** relieves upper airway obstruction and its physiologic consequences and represents the definitive treatment for obstructive sleep apnea. However, it has numerous adverse effects, including granuloma formation, difficulty with speech, and stoma and airway infection. Furthermore, the long-term care of the tracheotomy, especially in obese patients, can be difficult. Tracheotomy and other maxillofacial surgery approaches are reserved for patients with life-threatening arrhythmias or severe disability who have not responded to conservative therapy.

Some patients with sleep apnea have nocturnal bradycardia. A pilot study in 15 patients with either central or obstructive sleep apnea showed some improvement in oxygen saturation with atrial pacing. This single study must be considered preliminary.

Acute Respiratory Failure

Respiratory failure is defined as respiratory dysfunction resulting in abnormalities of oxygenation or ventilation (CO_2 elimination) severe enough to threaten the function of vital organs. Arterial blood gas criteria for respiratory failure are not absolute but may be arbitrarily established as a PO_2 under 60 mm Hg or a PCO_2 over 50 mm Hg. Acute respiratory failure may occur in a variety of pulmonary and nonpulmonary disorders (Table 9–24). A complete discussion of treatment of acute respiratory failure is beyond the scope of this chapter. Only a few selected general principles of management will be reviewed here.

Table 9–24. Selected causes of acute respiratory failure in adults.

Airway disorders	**Neuromuscular and related disorders**
Asthma	Primary neuromuscular diseases

Acute exacerbation of chronic bronchitis or emphysema	Guillain-Barré syndrome
Obstruction of pharynx, larynx, trachea, main stem bronchus, or lobar bronchus by edema, mucus, mass, or foreign body	Myasthenia gravis
Pulmonary edema	Poliomyelitis
Increased hydrostatic pressure	Polymyositis
Left ventricular dysfunction (eg, myocardial ischemia, heart failure)	Drug- or toxin-induced
Mitral regurgitation	Botulism
Left atrial outflow obstruction (eg, mitral stenosis)	Organophosphates
Volume overload states	Neuromuscular blocking agents
Increased pulmonary capillary permeability	Aminoglycosides
Acute respiratory distress syndrome	Spinal cord injury
Acute lung injury	Phrenic nerve injury or

	dysfunction
Unclear etiology	Electrolyte disturbances: hypokalemia, hypophosphatemia
Neurogenic	Myxedema
Negative pressure (inspiratory airway obstruction)	**Central nervous system disorders**
Reexpansion	Drugs: sedative, hypnotic, opioid, anesthetics
Tocolytic-associated	Brainstem respiratory center disorders: trauma, tumor, vascular disorders, hypothyroidism
Parenchymal lung disorders	Intracranial hypertension
Pneumonia	Central nervous system infections

Clinical Findings

Symptoms and signs of acute respiratory failure are those of the underlying disease combined with those of hypoxemia or hypercapnia. The chief symptom of hypoxemia is dyspnea, though profound hypoxemia may exist in the absence of complaints. Signs of hypoxemia include cyanosis, restlessness, confusion, anxiety, delirium, tachypnea, bradycardia or tachycardia, hypertension, cardiac dysrhythmias, and tremor. Dyspnea and headache are the cardinal symptoms of hypercapnia. Signs of hypercapnia include peripheral and conjunctival hyperemia, hypertension, tachycardia, tachypnea, impaired consciousness, papilledema, and asterixis. The symptoms and signs of acute respiratory failure are both insensitive and nonspecific; therefore, the physician must maintain a high index of suspicion and obtain arterial blood gas analysis if respiratory failure is suspected.

Treatment

Treatment of the patient with acute respiratory failure consists of (1) specific therapy directed toward the underlying disease; (2) respiratory supportive care directed toward the maintenance of adequate gas exchange; and (3) general supportive care. Only the last two aspects are discussed below.

Respiratory Support

Respiratory support has both nonventilatory and ventilatory aspects.

Nonventilatory aspects

The main therapeutic goal in acute hypoxemic respiratory failure is to ensure adequate oxygenation of vital organs. Inspired oxygen concentration should be the lowest value that results in an arterial hemoglobin saturation of 90% (PO_2 60 mm Hg). Higher arterial oxygen tensions are of no proven benefit. Restoration of normoxia may rarely cause hypoventilation in patients with chronic hypercapnia; however, *oxygen therapy should not be withheld for fear of causing progressive respiratory acidemia*. Hypoxemia in patients with obstructive airway disease is usually easily corrected by administering low-flow oxygen by nasal cannula (1–3 L/min) or Venturi mask (24–28%). Higher concentrations of oxygen are necessary to correct hypoxemia in patients with ARDS, pneumonia, and other parenchymal lung diseases.

Ventilatory aspects

Ventilatory support consists of maintaining patency of the airway and ensuring adequate alveolar ventilation. Mechanical ventilation may be provided via face mask (noninvasive) or through tracheal intubation.

Noninvasive positive-pressure ventilation

NPPV delivered via a full face mask or nasal mask has become first-line therapy in COPD patients with hypercapnic respiratory failure who can protect and maintain the patency of their airway, handle their own secretions, and tolerate the mask apparatus. Several studies have demonstrated the effectiveness of this therapy in reducing intubation rates and ICU stays in patients with ventilatory failure. Patients with acute lung injury or ARDS or those who suffer from severely impaired oxygenation do not benefit and should be intubated if they require mechanical ventilation. A bilevel positive pressure ventilation mode is preferred for most patients.

Tracheal intubation

Indications for tracheal intubation include: (1) hypoxemia despite supplemental oxygen, (2) upper airway obstruction, (3) impaired airway protection, (4) inability to clear secretions, (5) respiratory acidosis, (6) progressive general fatigue, tachypnea, use of accessory respiratory muscles, or mental status deterioration, and (7) apnea. In general, orotracheal intubation is preferred to nasotracheal intubation in urgent or emergency situations because it is easier, faster, and less traumatic. The position of the tip of the endotracheal tube at the level of the aortic arch should be verified by chest radiograph immediately following intubation, and auscultation should be performed to verify that both lungs are being inflated. Only tracheal tubes with high-volume, low-pressure air-filled cuffs should be used. Cuff inflation pressure should be kept below 20 mm Hg if possible to minimize tracheal mucosal injury.

Mechanical ventilation

Indications for mechanical ventilation include: (1) apnea, (2) acute hypercapnia that is not quickly reversed by appropriate specific therapy, (3) severe hypoxemia, and (4) progressive patient fatigue despite appropriate treatment.

Several modes of positive-pressure ventilation are available. Controlled mechanical ventilation (CMV; also known as assist-control or A-C) and synchronized intermittent mandatory ventilation (SIMV) are ventilatory modes in which the ventilator delivers a minimum number of breaths of a specified tidal volume each minute. In both CMV and SIMV, the patient may trigger the ventilator to deliver additional breaths. In CMV, the ventilator responds to breaths initiated by the patient above the set rate by delivering additional full tidal volume breaths. In SIMV, additional breaths are not supported by the ventilator unless the pressure support mode is added. Numerous alternative modes of mechanical ventilation now exist, the most popular being pressure support ventilation (PSV), pressure control ventilation (PCV), and CPAP.

PEEP is useful in improving oxygenation in patients with diffuse parenchymal lung disease such as ARDS. It should be used cautiously in patients with localized parenchymal disease, hyperinflation, or very high airway pressure requirements during mechanical ventilation.

Complications of mechanical ventilation

Potential complications of mechanical ventilation are numerous. Migration of the tip of the endotracheal tube into a main bronchus can cause atelectasis of the contralateral lung and overdistention of the intubated lung. **Barotrauma** (alternatively referred to as "volutrauma"), manifested by subcutaneous emphysema, pneumomediastinum, subpleural air cysts, pneumothorax, or systemic gas embolism (see x-ray), may occur in patients whose lungs are overdistended by excessive tidal volumes, especially those with hyperinflation caused by airflow obstruction. Subtle parenchymal lung injury due to overdistention of alveoli is another potential hazard. Strategies to avoid barotrauma include deliberate hypoventilation through the use of low mechanical tidal volumes and respiratory rates, resulting in "permissive hypercapnia."

Fig.
Barotrauma in ARDS. ***A:*** Chest radiograph demonstrates diffuse lung consolidation secondary to

ARDS. Parenchymal stippling is present, with lucent perivascular halos secondary to pulmonary interstitial emphysema. ***B:*** On chest radiograph 4 days later, pneumomediastinum is now identified with extensive subcutaneous emphysema. ***C:*** In another patient with ARDS, subpleural cysts *(arrow)* and parenchymal stippling due to pulmonary interstitial emphysema are present. (Reproduced, with permission, from Bongard FS, Sue DY [editors]: *Current Critical Care Diagnosis & Treatment*. Originally published by Appleton & Lange. Copyright © 1994 by The McGraw-Hill Companies, Inc.)

Acute respiratory alkalosis caused by overventilation is common. Hypotension induced by elevated intrathoracic pressure that results in decreased return of systemic venous blood to the heart may occur in patients treated with PEEP, those with severe airflow obstruction, and those with intravascular volume depletion. Ventilator-associated pneumonia is another serious complication of mechanical ventilation.

General Supportive Care

Maintenance of adequate nutrition is vital; parenteral nutrition should be used only when conventional enteral feeding methods are not possible. Overfeeding, especially with carbohydrate-rich formulas, should be avoided, because it can increase CO_2 production and may potentially worsen or induce hypercapnia in patients with limited ventilatory reserve. However, failure to provide adequate nutrition is more common. Hypokalemia and hypophosphatemia may worsen hypoventilation due to respiratory muscle weakness. Sedative-hypnotics and opioid analgesics are frequently used. They should be titrated carefully to avoid oversedation, leading to prolongation of intubation. Temporary paralysis with a nondepolarizing neuromuscular blocking agent is occasionally used to facilitate mechanical ventilation and to lower oxygen consumption. Prolonged muscle weakness due to an acute myopathy is a potential complication of these agents. Myopathy is more common in patients with kidney dysfunction and in those given concomitant corticosteroids.

Psychological and emotional support of the patient and family, skin care to avoid decubitus ulcers, and meticulous avoidance of health care–associated infection and complications of tracheal tubes are vital aspects of comprehensive care for patients with acute respiratory failure.

Attention must also be paid to preventing complications associated with serious illness. Stress gastritis and ulcers may be avoided by administering sucralfate, histamine H_2-receptor antagonists, or proton pump inhibitors. There is some concern that the latter two agents, which raise the gastric pH, may permit increased growth of gram-negative bacteria in the stomach, predisposing to pharyngeal colonization and ultimately health care–associated pneumonia; many clinicians therefore prefer sucralfate. The risk of DVT and PE may be reduced by subcutaneous administration of heparin (5000 units every 12 hours), the use of LMWH, or placement of a sequential compression device on an extremity.

Course & Prognosis

The course and prognosis of acute respiratory failure vary and depend on the underlying disease. The prognosis of acute respiratory failure caused by uncomplicated sedative or narcotic drug overdose is excellent. Acute respiratory failure in patients with COPD who do not require intubation and mechanical ventilation has a good immediate prognosis. On the other hand, ARDS associated with sepsis has an extremely poor prognosis, with mortality rates of about 90%. Overall, adults requiring mechanical ventilation for all causes of acute respiratory failure have survival rates of 62% to weaning, 43% to hospital discharge, and 30% to 1 year after hospital discharge.

Acute Respiratory Distress Syndrome

Essentials of Diagnosis

- Acute onset of respiratory failure.
- Bilateral radiographic pulmonary infiltrates.
- Absence of elevated left atrial pressure (if measured, pulmonary capillary wedge pressure   18 mm Hg).
- Ratio of partial pressure of oxygen in arterial blood (PaO_2) to fractional concentration of inspired oxygen (FIO_2) < 200, regardless of the level of PEEP.

General Considerations

ARDS denotes acute hypoxemic respiratory failure following a systemic or pulmonary insult without evidence of heart failure. ARDS is the most severe form of acute lung injury and is characterized by bilateral, widespread radiographic pulmonary infiltrates, normal pulmonary capillary wedge pressure (18 mm Hg) and a PaO_2/FIO_2 ratio < 200. ARDS may follow a wide variety of clinical events (Table 9–25). Common risk factors for ARDS include sepsis, aspiration of gastric contents, shock, infection, lung contusion, nonthoracic trauma, toxic inhalation, near-drowning, and multiple blood transfusions. About one-third of ARDS patients initially have sepsis syndrome. Pro-inflammatory cytokines released from stimulated inflammatory cells appear to be pivotal in lung injury. Although the mechanism of lung injury varies with the cause, damage to capillary endothelial cells and alveolar epithelial cells is common to ARDS regardless of cause. Damage to these cells causes increased vascular permeability and decreased production and activity of surfactant; these abnormalities lead to interstitial and alveolar pulmonary edema, alveolar collapse, and hypoxemia.

Table 9–25. Selected disorders associated with ARDS.

Systemic Insults	**Pulmonary Insults**
Trauma	Aspiration of gastric contents
Sepsis	Embolism of thrombus, fat, air, or amniotic fluid
Pancreatitis	Miliary tuberculosis

Shock	Diffuse pneumonia (eg, SARS)
Multiple transfusions	Acute eosinophilic pneumonia
Disseminated intravascular coagulation	Cryptogenic organizing pneumonitis
Burns	Upper airway obstruction
Drugs and drug overdose	Free-base cocaine smoking
Opioids	Near-drowning
Aspirin	Toxic gas inhalation
Phenothiazines	Nitrogen dioxide
Tricyclic antidepressants	Chlorine
Amiodarone	Sulfur dioxide
Chemotherapeutic agents	Ammonia
Nitrofurantoin	Smoke
Protamine	Oxygen toxicity
Thrombotic thrombocytopenic purpura	Lung contusion
Cardiopulmonary bypass	Radiation exposure
Head injury	High-altitude exposure
Paraquat	Lung reexpansion or reperfusion

ARDS, acute respiratory distress syndrome; SARS, severe acute respiratory syndrome.

Clinical Findings

ARDS is marked by the rapid onset of profound dyspnea that usually occurs 12–48 hours after the initiating event. Labored breathing, tachypnea, intercostal retractions, and crackles are noted on physical examination (see x-ray). Chest radiography shows diffuse or patchy bilateral infiltrates that rapidly become confluent; these characteristically spare the costophrenic angles (see x-ray). Air bronchograms occur in about 80% of cases. Upper lung zone venous engorgement is distinctly uncommon. Heart size is normal, and pleural effusions are small or nonexistent. Marked hypoxemia occurs that is refractory to treatment with supplemental oxygen. Many patients with ARDS demonstrate multiple organ failure, particularly involving the kidneys, liver, gut, central nervous system, and cardiovascular system.

Fig.
ARDS secondary to sepsis in an immunocompromised

patient following bone marrow transplantation. ***A:*** Stage I ARDS. The initial chest radiograph is normal despite marked dyspnea and hypoxemia. ***B:*** Stage II ARDS. Within 24 hours, the chest radiograph shows diffuse parenchymal opacification consistent with ARDS. Differential Diagnosis

Since ARDS is a physiologic and radiographic syndrome rather than a specific disease, the concept of differential diagnosis does not strictly apply. Normal-permeability ("cardiogenic" or hydrostatic) pulmonary edema must be excluded (see x-ray), however, because specific therapy is available for that disorder. Measurement of pulmonary capillary wedge pressure by means of a flow-directed pulmonary artery catheter may be required in selected patients with suspected cardiac dysfunction. Routine use of the Swan-Ganz catheter in ARDS is discouraged.

Fig.

Pulmonary edema. The heart is enlarged, and there is a left pleural effusion. The pulmonary vasculature is prominent, particularly in the upper zones and perihilar areas, with bilateral distribution of thick vessels giving a butterfly or batwing appearance. (Courtesy of H Goldberg.)

Prevention

No measures that effectively prevent ARDS have been identified; specifically, prophylactic use of PEEP in patients at risk for ARDS has not been shown to be effective. Intravenous methylprednisolone does not prevent ARDS when given early to patients with sepsis syndrome or septic shock.

Treatment

Treatment of ARDS must include identification and specific treatment of the underlying precipitating and secondary conditions (eg, sepsis). Meticulous supportive care must then be provided to compensate for the severe dysfunction of the respiratory system associated with ARDS and to prevent complications (see above).

Treatment of the hypoxemia seen in ARDS usually requires tracheal intubation and positive-pressure mechanical ventilation. The lowest levels of PEEP (used to recruit atelectatic alveoli) and supplemental oxygen required to maintain the PaO_2 above 60 mm Hg or the SaO_2 above 90% should be used. Efforts should be made to decrease FIO_2 to less than 60% as soon as possible in order to avoid oxygen toxicity. PEEP can be increased as needed as long as cardiac output and oxygen delivery do not decrease and airway pressures do not increase excessively. Prone positioning may transiently improve oxygenation in selected patients by helping recruit atelectatic alveoli; however, great care must be taken during the maneuver to avoid dislodging catheters and tubes.

A variety of mechanical ventilation strategies are available. A multicenter study of 800 patients demonstrated that a protocol using volume-cycled ventilation with low tidal volumes (6 mL/kg of ideal body weight) resulted in a 10% absolute mortality reduction over therapy with standard tidal volumes (defined as 12 mL/kg of ideal body weight); this trial reported the lowest mortality (31%) of any intervention to date for ARDS.

Cardiac output that falls when PEEP is used may be improved by reducing the level of PEEP or by the judicious use of inotropic drugs (eg, dopamine); administering fluids to increase intravascular volume should be done only with great caution, because increases in pulmonary capillary pressure worsen pulmonary edema in the presence of increased capillary permeability.

Therefore, the goal of fluid management is to maintain pulmonary capillary wedge pressure at the lowest level compatible with adequate cardiac output. Crystalloid solutions should be used when intravascular volume expansion is necessary. Diuretics should be used to reduce intravascular volume if pulmonary capillary wedge pressure is elevated.

Oxygen delivery can be increased in anemic patients by ensuring that hemoglobin concentrations are at least 7 g/dL; patients are not likely to benefit from higher levels. Increasing oxygen delivery to supranormal levels through the use of inotropes and high hemoglobin concentrations is not clinically useful and may be harmful. Strategies to decrease oxygen consumption include the appropriate use of sedatives, analgesics, and antipyretics.

A large number of innovative therapeutic interventions to improve outcomes in ARDS patients have been or are being investigated. Unfortunately, to date, none have consistently shown benefit in clinical trials. Systemic corticosteroids have been studied extensively with variable and inconsistent results. While recent studies suggest some specific improved outcomes when given within the first 2 weeks after the onset of ARDS, the routine use of corticosteroids is not recommended.

Course & Prognosis

The mortality rate associated with ARDS is 30–40%. If ARDS is accompanied by sepsis, the mortality rate may reach 90%. The major causes of death are the primary illness and secondary complications such as multiple organ system failure or sepsis. Median survival is about 2 weeks. Many patients who succumb to ARDS and its complications die after withdrawal of support (see Withdrawal of Curative Efforts in Chapter 5: Palliative Care & Pain Management). Most survivors of ARDS are left with some pulmonary symptoms (cough, dyspnea, sputum production), which tend to improve over time. Mild abnormalities of oxygenation, diffusing capacity, and lung mechanics persist in some individuals.

Common Symptoms

The most common symptoms of heart disease are dyspnea, chest pain, palpitations, syncope or presyncope, and fatigue. None are specific, and interpretation depends on the entire clinical picture and, in many cases, diagnostic testing.

Chest Pain or Discomfort

Chest pain and other forms of discomfort are common symptoms that can occur as a result of pulmonary, pleural, or musculoskeletal disease, esophageal or other gastrointestinal disorders, or anxiety states, as well as many cardiovascular diseases. Myocardial ischemia is a frequent cause of cardiac chest pain and is usually described as dull, aching, or as a sensation of "pressure," "tightness," "squeezing," or "gas," rather than as sharp or spasmodic. **Ischemic symptoms** frequently are first noted only with exercise or cardiac stress from cold exposure, meals, or a combination of factors and often resolve quickly once the inciting event is over. Progressive symptoms or symptoms at rest may represent unstable angina due to coronary plaque rupture and thrombosis. Protracted episodes often represent **myocardial infarction**, although one-third of patients with acute myocardial infarction do not have chest pain. When present, the pain is commonly accompanied by a sense of anxiety or uneasiness. The location is usually retrosternal or left precordial. Because there are not the appropriate sensory nerves on the heart, the central nervous system interpretation of pain location often results in pressure or "heaviness" being referred to the throat, lower jaw, shoulders, inner arms, upper abdomen, or back. Ischemic pain is not related to position or respiration and is usually not elicited by chest palpation. One clue that the pain may be ischemic is the presence of other symptoms associated with the pain, such as shortness of breath, dizziness, a feeling of impending doom, and vagal symptoms, such as nausea and diaphoresis. Of importance, depression may mask symptoms, especially in women.

Hypertrophy of either ventricle, such as in aortic stenosis or hypertrophic cardiomyopathy, may result in subendocardial underperfusion during stress and may also give rise to atypical ischemic pain. Myocarditis, pulmonary hypertension, and mitral valve prolapse are also associated with chest pain atypical for angina pectoris. Pericarditis may produce pain that is greater supine than upright, and may increase with respiration, or swallowing. Pleuritic chest pain is not ischemic, and pain on palpation should signal a musculoskeletal etiology. Aortic dissection classically produces an abrupt onset of tearing pain of great intensity that often radiates to the back.

treatment history in the prediction of cardiac risk in women with suspected myocardial ischemia: the NHLBI-sponsored WISE study. Arch Gen Psychiatry. 2006 Aug;63(8):874–80. [PMID: 16894063]

Dyspnea

Dyspnea due to heart disease is generally precipitated or exacerbated by exertion and usually results from elevated left atrial (LA) and pulmonary venous pressures or from hypoxia, though some patients with purely right heart disease complain of dyspnea as well. The former are most commonly caused by left ventricular (LV) systolic dysfunction, LV diastolic dysfunction (due to hypertrophy, fibrosis, or pericardial disease), or valvular stenosis or regurgitation. Exertional dyspnea may be an anginal equivalent. The acute onset or worsening of LA hypertension may result in **pulmonary edema** (see x-ray); (see x-ray). **Hypoxia** may be a consequence of pulmonary edema, inherent lung disease, or right to left shunting. Dyspnea should be quantified by asking if commonly performed tasks can precipitate it, such as climbing stairs, housework, grocery shopping, mowing the lawn, vacuuming, etc. It is also a common symptom of primary and secondary pulmonary disease, and the etiologic distinction may be difficult. The diagnosis of congestive heart failure (CHF) may be aided by measurement of B-type natriuretic peptide (BNP) or N terminal pro-BNP (pro-BNP), though high levels may also result from right ventricular (RV) dysfunction and pulmonary embolism. Shortness of breath may also occur in sedentary or obese individuals who have reduced lung capacity and is also associated with anxiety states, anemia, and many other illnesses.

Fig.

Pulmonary edema. (Courtesy of H Goldberg.)

(Reproduced, with permission, from Cheitlin MD, Sokolow M, McIlroy MB: *Clinical Cardiology*, 6th ed. Originally published by Appleton & Lange. Copyright © 1993 by The McGraw-Hill Companies, Inc.)

Orthopnea is dyspnea that occurs in recumbency and results from an increase in central blood volume when supine. It may also result from pulmonary disease and obesity. **Paroxysmal nocturnal dyspnea** is shortness of breath that occurs abruptly 30 minutes to 4 hours after going to bed and is relieved after 10 or 20 minutes by sitting up or standing up; this symptom is more specific for cardiac disease.

Green SM et al. Clinical uncertainty, diagnostic accuracy, and outcomes in emergency department patients presenting with dyspnea. Arch Intern Med. 2008 Apr 14;168(7):741–8. [PMID: 18413557]

Palpitations, Dizziness, Syncope

Palpitations, or awareness of the heartbeat, may be a normal phenomenon or may reflect increased cardiac or stroke output in patients with many noncardiac conditions (eg, exercise, thyrotoxicosis, anemia, anxiety). It may also be due to cardiac abnormalities that increase stroke volume (regurgitant valvular disease, bradycardia) or may be a manifestation of cardiac dysrhythmias. Ventricular premature beats may be sensed as extra or "skipped" beats; the patient usually senses a strong beat following a premature beat due to the higher stroke volume from the post-extrasystolic beat. Supraventricular or ventricular tachycardia may be felt as rapid, regular or irregular palpitations or "fluttering" (see ECG); (see ECG). If they result in a decrease in the systemic blood pressure, they may result in presyncope or syncope—especially in the upright position. However, **dizziness** in particular is nonspecific and is an uncommon symptom of cardiac disease or dysrhythmia.

Fig.

Paroxysmal supraventricular tachycardia. A regular, narrow complex tachycardia at a rate of 190/min is present. P waves immediately follow the QRS complexes (best seen in V_1 and V_2). Verification of this tachycardia as paroxysmal supraventricular tachycardia would depend on identifying inverted P waves in the inferior leads. (Reproduced, with permission, from Goldschlager N, Goldman MJ: *Principles of Clinical Electrocardiography*, 13th ed. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Fig.

Rapid ventricular tachycardia (rate 215/min). The mean frontal plane QRS axis is directed rightward and superiorly. A pure R wave configuration is present in lead V_1 and an RS configuration in V_6. P waves occurring in 1:1 relationship to the tachycardia complexes are best seen in leads II and V_{1-2}; they appear to be inverted in lead II and thus represent retrograde atrial activation. The origin of this tachycardia was confirmed at electrophysiologic study. (Reproduced, with permission, from Goldschlager N, Goldman MJ: *Principles of Clinical Electrocardiography*, 13th ed. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Cardiogenic syncope most commonly results from bradyarrhythmias (sinus node arrest or exit block, atrioventricular [AV] conduction block), very rapid supraventricular rhythms or ventricular tachycardia or fibrillation (see ECG); (see ECG). It often occurs at rest, and there may be no premonitory symptoms. Although recovery is often immediate, some patients may exhibit seizure-like movements. Aortic stenosis and hypertrophic obstructive cardiomyopathy may also cause syncope, but this generally only occurs with exertion. Another form of syncope is termed **neurocardiogenic syncope** or vasovagal syncope; it occurs when there is an inappropriate increase in vagal efferent activity, often resulting from a precedent increase in sympathetic cardiac stimulation. Syncope may follow presyncopal symptoms and may be either associated with a brief period of nausea and/or diaphoresis, or it may be abrupt in onset.

Autonomic dysfunction due to venous insufficiency or peripheral neuropathy can result in a positional fall in blood pressure (BP), and supine and upright BPs should be checked in all patients with syncope. Carotid sinus hypersensitivity may also result in syncope that is related to stimulation of the baroreceptors in the carotid sinus. Gentle carotid massage while monitoring the BP and cardiac rhythm usually can elicit the response. Carotid sinus hypersensitivity may be manifested by a cardio-inhibitor response, a vasodilatory response, or both.

Fig.
Complete atrioventricular (AV) block. The atrial rhythm is regular at a rate of 82/min. The ventricular rhythm is regular at a rate of 60/min. There is no relation between the two rhythms; the atria respond to the sinus node and the ventricles respond to an independent pacemaker. Since the QRS complexes are of normal duration and configuration, the ventricular pacemaker is likely to originate in the AV junction or bundle of His. The apparent widening of some of the QRS complexes (fifth QRS in lead III and third QRS in lead aVF) is the result of fortuitous superimposition of the P wave upon the QRS complex. Functional Classification of Heart Disease

In the management of patients with heart disease, it is important to quantify and monitor the severity of symptoms. A commonly used classification system is that of the New York Heart Association (NYHA), shown below. However, in monitoring individual patients, it is better to document specific activities that produce symptoms, such as walking a distance; climbing stairs; or performing activities of daily living, such as using a vacuum sweeper or going grocery shopping.

Class I: No limitation of physical activity. Ordinary physical activity does not cause undue fatigue, dyspnea, or anginal pain.
Class II: Slight limitation of physical activity. Ordinary physical activity results in symptoms.
Class III: Marked limitation of physical activity. Comfortable at rest, but less than ordinary activity causes symptoms.
Class IV: Unable to engage in any physical activity without discomfort. Symptoms may be present even

at rest.

Other classifications have been proposed, but these are universally accepted, and clinically can be applied to both heart failure and anginal symptoms. Some experts use the category of **Class V** to describe symptoms that are atypical and can occur either at rest or with exertion.

A task force from the American College of Cardiology/American Heart Association (ACC/AHA) proposed that patients with heart failure be classified into four stages:

Stage A: Those at high risk for congestive heart failure (CHF) but no structural heart disease (ie, hypertension, coronary artery disease [CAD]) and no symptoms.

Stage B: Those with structural heart disease associated with CHF and no symptoms.

Stage C: Those with structural heart disease who have current or prior symptoms.

Stage D: Those with refractory CHF requiring some device or special intervention.

Bonow RO et al. ACC/AHA clinical performance measures for adults with chronic heart failure: a report of the American College of Cardiology/American Heart Association Task Force on Performance Measures

(Writing Committee to Develop Heart Failure Clinical Performance Measures) endorsed by the Heart Failure Society of America. J Am Coll Cardiol. 2005 Sep 20;46(6):1144–78. [PMID: 16168305]

Signs of Heart Disease

Although the cardiovascular examination centers on the heart, peripheral signs often provide important information.

Appearance

Although cardiac patients may appear healthy and comfortable at rest, many with acute myocardial infarction appear anxious and restless. Diaphoresis may result from hypotension due to pericardial tamponade, tachyarrhythmias, myocardial infarction, or the presence of a high vagal state. Cold and clammy skin or pallor suggests low cardiac output and may be a sign of cardiogenic shock or anemia. Patients with severe chronic CHF or other long-standing low cardiac output states may appear **cachectic**.

Cyanosis may be *central*, due to arterial desaturation, or *peripheral*, reflecting impaired tissue delivery of adequately saturated blood in low-output states, polycythemia, or peripheral vasoconstriction. Clubbing may be present in chronic cyanotic states. Central cyanosis may be caused by pulmonary disease, left heart failure, or right-to-left intracardiac or intrapulmonary shunting; the latter will not be improved by increasing the inspired oxygen concentration. Edema may be present and its pitting nature and extent quantified. Note also if presacral edema is present. Severe right heart failure may also present with ascites and scrotal edema.

Vital Signs

Although the normal resting **heart rate** usually ranges from 50 to 90 beats/min, both slower and more rapid rates may occur in normal individuals or may reflect noncardiac conditions such as anxiety or pain, medication effect, fever, thyroid disease, pulmonary disease, anemia, or hypovolemia. If symptoms or clinical suspicion warrants, an ECG should be performed to diagnose arrhythmia, conduction disturbance, or other abnormalities. The range of normal BP is wide, but even in asymptomatic individuals systolic pressures below 90 mm Hg or above 140 mm Hg and diastolic pressures above 90 mm Hg warrant further clinical evaluation and follow-up. BP may vary between the upper extremities (often the left brachial is slightly lower than the right) and the BP measurement in the leg is usually higher than in the arm. Anxiety may increase the BP, and the patient should be asked if it has been checked in other settings. The ready availability of home BP monitoring or drugstore monitoring units should be considered before beginning antihypertensive therapy if the BP is borderline elevated. **Tachypnea** is also nonspecific, but pulmonary disease and heart failure should be considered when respiratory rates exceed 16/min under resting conditions. Cheyne–Stokes respiration, a form of **periodic breathing** is not uncommon in severe heart failure.

Peripheral Pulses & Venous Pulsations

The quality or magnitude of the pulses palpated is a reflection of the pulse pressure. **Diminished peripheral pulses** most commonly result from arteriosclerotic peripheral vascular disease and may be accompanied by localized **bruits**. Asymmetry of pulses should also arouse suspicion of coarctation of the aorta or aortic dissection, especially if a delay is noted between the brachial or radial pulse and the femoral pulse. **Exaggerated upper extremity pulses** may indicate aortic regurgitation, coarctation, patent ductus arteriosus, or other conditions that increase stroke volume. The carotid pulse is a valuable aid to assessment of LV ejection. It has a **delayed upstroke** in aortic stenosis and a **bisferiens** quality (two palpable peaks) in mixed aortic stenosis and regurgitation or hypertrophic obstructive cardiomyopathy. The pulse may be difficult to feel in significant aortic stenosis or in low output states. **Pulsus paradoxus** (a decrease in systolic BP during inspiration) is a normal sign unless exaggerated to > 10 mm Hg. The most common cause of pulsus paradoxus is asthma and chronic obstructive pulmonary disease (see ECG), though its presence may be a critical component to the diagnosis of pericardial tamponade. **Pulsus alternans**, in which the amplitude of the pulse alternates every other beat during sinus rhythm, occurs when cardiac contractility is very depressed. It is volume dependent and at times can only be elicited by feeling the pulse on standing.

Fig.

Pulsus paradoxus in right and left ventricular pressure tracings in a patient with chronic constrictive pericarditis. (Reproduced, with permission, from Cheitlin MD, Sokolow M, McIlroy MB: *Clinical Cardiology*, 6th ed. Originally published by Appleton & Lange. Copyright © 1993 by The McGraw-Hill Companies, Inc.)

Jugular venous pulsations (JVP) provide insight into right atrial (RA) pressure (see illustration) and function. To identify the waveforms, it is important to palpate the opposite carotid pulse while simultaneously observing the JVP. During ventricular systole (a positive carotid pulse wave), the normal RA pressure falls due to both atrial diastole and the pulling of the tricuspid valve into the RV cavity (the *x* descent). In the JVP, a prominent waveform just prior to systole is the *a* wave. A prominent waveform just after systole is the v wave. A waveform during systole is the *c-v* wave. **Prominent *a* waves** imply poor RV compliance or atrial contraction against a closed tricuspid valve (due to AV dissociation associated with ventricular arrhythmias, pacing, or tricuspid stenosis). A **prominent *v* wave** implies rapid filling of the RA, such as in an atrial septal defect (ASD) or mild tricuspid regurgitation, and a ***c-v* wave** implies significant tricuspid regurgitation. The height of the JVP provides a measure of RA pressure with an **elevated central venous pressure** if it is visible above the angle of Louis with the patient upright. An increased central blood volume and reduced RV compliance can also be assumed if the JVP rise more than 1 cm and are sustained (> 20 seconds) by right upper quadrant abdominal pressure **(the hepatojugular reflux)** (see ECG). **Kussmaul sign** (failure of jugular venous pressure to decrease with inspiration) is commonly seen with RV infarction, postoperatively after cardiac surgery, with tricuspid regurgitation, and with constrictive pericarditis.

Fig.

Examination of jugular venous pulse and estimation of venous pressure. (RA, right atrium; RV, right ventricle.) In any body position, the sternal angle is 5 cm above the right atrium. Pulmonary Examination

Rales heard at the lung bases are a sign of CHF but may be caused by similarly localized pulmonary disease . Cardiac rales tend to occur late in inspiration and be fine in nature, while pulmonary rales tend to be more coarse and appear in early or mid inspiration. Rales are loudest at the bases in heart failure, and the examiner should note how far up from the diaphragm they are audible. The so-called stress-relaxation quadruple hypothesis of crackle generation holds that expiratory crackles are caused by sudden airway closure events that are similar in mechanism but opposite in sign and far less energetic than the explosive opening events that generate inspiratory crackles. The most likely mechanism of crackle generation is sudden airway closing during expiration and sudden airway reopening during inspiration. **Wheezing** suggests obstructive pulmonary disease and only rarely occurs in left heart failure ; . **Pleural effusions** with bibasilar percussion dullness and reduced breath sounds are common in CHF and are more frequent or larger on the right (see x-ray). Egophony may be present due to pulmonary compression over a pleural effusion or to a pulmonary infiltration.

Audio

Recording of a person with early congestive heart failure. The lung sounds of early congestive heart failure are very similar to those of pulmonary fibrosis. The fine end-inspiratory rales of the two diseases are difficult to distinguish. (Reproduced, with permission, from Murphy RLH Jr: *A Simplified Introduction to Lung Sounds* [audio tape], 1977.)

Precordial Pulsations

A **parasternal lift** usually indicates right ventricular hypertrophy (RVH), pulmonary hypertension (pulmonary artery [PA] systolic pressure > 50 mm Hg), or LA enlargement; PA pulsations may also be visible. The examiner should feel the LV apical impulse in the left lateral position and note if it is sustained or enlarged and whether an early impulse (*A* wave) precedes the main apical thrust. The *A* wave implies poor LV compliance and corresponds to a fourth heart sound. If the second heart sound is palpable along the left sternal border, it may imply an increased P_2 and pulmonary hypertension.

Heart Sounds & Murmurs

Auscultation is helpful in the diagnosis of many heart diseases, and provides evidence for cardiac failure (see ECG). Specific findings are discussed under individual diseases below.

Fig.

The timing of the principal cardiac murmurs. (Modified and reproduced, with permission, from Wood P:

Diseases of the Heart and Circulation, 3rd ed. Lippincott, 1968.)

The **first heart sound** (S_1), the closing of the mitral valve and tricuspid valve, may be diminished with severe LV dysfunction or accentuated with mitral stenosis or short PR intervals. Separation of the components of **the second heart sound** is due to the normally compliant lung, allowing for continuing forward pulmonary flow with systole compared to the aortic flow into the less compliant systemic arterial system. The pulmonary valve closes later than the aortic valve for that reason (and results in P_2 following A_2). Inspiration increases flow to the lung and reduces flow to the left heart, and splitting is increased by increasing the RV stroke volume. **Splitting** may be *fixed* in atrial septal defect , *wide* with right bundle branch block, and *absent* or *reversed* **(paradoxic splitting)** with aortic stenosis, LV failure, or left bundle branch block. With normal splitting, an accentuated P_2 is an important sign of pulmonary hypertension . Splitting may widen if the RV ejection prolongs due to the increased afterload on the RV. **Third and fourth heart sounds** (ventricular and atrial gallops, respectively) indicate ventricular volume overload or impaired compliance and may be heard over either ventricle (;). A right-sided gallop may increase with inspiration or may be confirmed if heard in the right subclavicular area (where a left-sided gallop does not usually radiate). A palpable *A* wave helps confirm an S_4. An apical S_3 is a normal finding in younger individuals and in high output states, such as pregnancy. Additional auscultatory findings include sharp, high-pitched sounds classified as **"clicks."** These may be early systolic and represent **ejection sounds** (as with a bicuspid aortic valve or pulmonary stenosis) or may occur in mid or late systole, indicating myxomatous changes in the mitral valve .

Audio
Atrial septal defect (ASD) and pulmonary hypertension. Note S1 followed by a rough systolic murmur and fixed close splitting of A2-P2. P2 is louder than A2. (Reproduced, with permission, from T. Anthony Don Michael, MD: *Mastering Auscultation* [CD-ROM], 2000.)

Audio
Pulmonary hypertension. Note the rough mid-systolic murmur followed by a split S2 with a lout P2. (Reproduced, with permission, from T. Anthony Don Michael, MD: *Mastering Auscultation* [CD-ROM], 2000.)

Audio
Congestive heart failure due to valvular dysfunction. Note the holosystolic murmur and S2 followed by S3. (Reproduced, with permission, from T. Anthony Don Michael, MD: *Mastering Auscultation* [CD-ROM], 2000.)
Audio
An S4 precedes S1 and is an abnormal finding in this pregnant patient. Peripartum cardiomyopathy must be considered. (Reproduced, with permission, from T. Anthony Don Michael, MD: *Mastering Auscultation* [CD-ROM], 2000.)
Audio
Mitral valve prolapse with S1, non-ejection click, late systolic murmur, and S2. (Reproduced, with permission, from T. Anthony Don Michael, MD: *Mastering Auscultation* [CD-ROM], 2000.)

Although many **murmurs** indicate valvular disease, a soft, short systolic murmur, usually localized along the left sternal border or toward the apex, may be innocent, reflecting pulmonary or aortic flow. **Innocent murmurs** often vary with inspiration, diminish in the upright position, and are most frequently heard in thin individuals. **Systolic murmurs** should be classified as **"holosystolic"** when they merge with S_1 and persist through S_2 or **"ejection"** when they begin after S_1 and end before S_2. Holosystolic murmurs tend to have a uniform intensity during systole, while ejection murmurs have a peak at some part of the systolic cycle. Holosystolic murmurs usually represent mitral regurgitation if maximal at the apex or in the axilla and tricuspid regurgitation or ventricular septal defect (VSD) if best heard at the sternal border. Short aortic ejection murmurs with a preserved A_2 are common in older individuals, especially when hypertension has been present, and even if they are moderately loud they usually reflect thickening (sclerosis) of the valve and may not imply aortic stenosis. The association of murmurs with palpable vibrations **("thrills")** is always clinically significant (except in the case of a tiny VSD where there is a high gradient between the LV and RV), as are **diastolic murmurs**. High-pitched diastolic murmurs imply flow from a high-pressure to low-pressure chamber (ie, pulmonic regurgitation in pulmonary hypertension, aortic regurgitation, or VSD) while low-pitched diastolic "rumbles" imply filling across an AV valve (ie, mitral stenosis). Further evaluation is warranted when the patient has symptoms of possible cardiac origin. An echocardiogram should be ordered whenever a murmur is heard.

Audio
Mitral regurgitation causing heart failure. Note the holosystolic murmur heard best at the apex, followed by S2 and an S3. (Reproduced, with permission, from T. Anthony Don Michael, MD: *Mastering Auscultation* [CD-ROM], 2000.)
Audio
Tricuspid regurgitation due to tricuspid valve endocarditis. A blowing holosystolic murmur is preceded by S1, followed by S2, and increases in loudness with inspiration. (Reproduced, with permission, from T. Anthony Don Michael, MD: *Mastering Auscultation* [CD-ROM], McGraw-Hill, 2000.)
Audio
Ventricular septal defect (VSD). Blowing to rough grade 4/6 holosystolic murmur. A VSD may cause a loud rough murmur rather than a more characteristic blowing murmur. (Reproduced, with permission, from T. Anthony Don Michael, MD: *Mastering Auscultation* [CD-ROM], 2000.)

Audio
Pulmonary regurgitation due to primary pulmonary hypertension. Note the loud P2 followed by a rapidly attenuating early diastolic murmur. (Reproduced, with permission, from T. Anthony Don Michael, MD: *Mastering Auscultation* [CD-ROM], 2000.)

Edema

Subcutaneous fluid collections appear first in the lower extremities in ambulatory patients or in the sacral region of bedridden individuals. In heart disease, edema primarily results from elevated RA pressures or associated peripheral venous disease. Right heart failure most commonly results from left heart failure, pulmonary disease, or RV dysfunction and tricuspid regurgitation, or constrictive pericarditis. Edema may also be due to nephrotic syndrome, low serum albumin, cirrhosis, premenstrual fluid retention, or drugs (especially vasodilators such as calcium channel blockers or salt-retaining medications such as nonsteroidal anti-inflammatory agents or thiazolidinedione diabetic agents), or it may be idiopathic. The presence of ascites may predominate over the presence of peripheral edema, especially in constrictive pericarditis with associated cardiac cirrhosis, or following aggressive diuretic usage that reduces peripheral edema.

Diagnostic Testing

The **chest radiograph** provides information about heart size (with cardiomegaly being a poor prognostic sign in chronic heart failure), the pulmonary circulation (with characteristic signs suggesting both pulmonary arterial or pulmonary venous hypertension), primary pulmonary disease, and aortic abnormalities (see x-ray). Individual chamber sizes can be estimated, and the presence of pleural effusions noted. The **echocardiogram**, though, provides more reliable cardiac information than the chest radiograph about chamber size and hypertrophy, and the presence of pericardial effusions, valvular abnormalities, and congenital abnormalities (see Video). The **ECG** indicates cardiac rhythm, reveals conduction abnormalities, and provides evidence of ventricular hypertrophy, myocardial infarction, or ischemia (see ECG); (see ECG). ST segment and T wave changes may reflect these processes but are also noted with electrolyte imbalance, drug effects, and many other conditions (see ECG). Routine radiographs and ECGs are not recommended to screen for heart disease. **Stress testing** is useful in eliciting ischemia due to fixed coronary lesions, but its use in the typical asymptomatic patient is limited. For instance, it is useful to recall Bayes theorem when contemplating stress testing patients as part of an "executive physical." Bayes theorem states that the results of a test depend on the risk of disease. If the patient is at low risk for CAD, for instance, one can expect a high number of false-positive stress results. If the patient is at high risk for CAD, one can expect a high number of false-negative results. Stress studies are most effective in those with an intermediate risk for CAD. The clinician's goal is to help define the CAD risk using the history, physical examination, and other available laboratory tests (see below). Stress testing may also be useful in non-CAD patients whenever symptoms seem disproportionate to anatomic defects. For instance, in valvular disease, if the patient is complaining of major symptoms but has only minor anatomic disease, a stress study may help define exercise capacity. Similarly, if there is significant disease by echocardiography, but few or no symptoms, the stress study may define an unrecognized disability. **Blood chemistry tests** play a major role in defining cardiac risk factors (ie, serum lipid levels, serum human C-reactive protein [hCRP] level, creatinine) and can help with determining etiology of symptoms (ie, BNP level).

Fig.

Marked, diffuse ST-segment depression with T wave inversion recorded in a patient with three-vessel coronary artery disease during an episode of anginal pain. Tracings before and after the pain were entirely normal. ST-segment depression is most prominent in II, III, aVF, and V_{2-6}; in leads V_{3-5} the ST depression is 10 mm. (Reproduced, with permission, from Goldschlager N, Goldman MJ: *Principles of Clinical Electrocardiography*, 13th ed. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Fig.

Left ventricular hypertrophy in a patient with aortic regurgitation. The R wave in aVL is 13 mm, and SV_1 RV_6 is 47 mm. Associated ST elevation is present in leads V_{1-3} and ST depression in I, aVL, and V_{5-6}. QS complexes are present in V_{1-4}. In the presence of left ventricular hypertrophy, criteria for myocardial infarction cannot be accurately applied. Noninvasive Diagnostic Imaging for Noncoronary Heart Disease

The diagnostic procedures for CAD will be discussed in the following section on Coronary Cardiology. Reviewed here is the use of noninvasive testing for noncoronary heart disease.

Echocardiography & Doppler Ultrasound Imaging

Two-dimensional echocardiography provides information regarding all four chamber sizes, regional and global systolic function, and chamber wall thickness (see Video). Excellent images of valve motion, intracardiac masses, abnormal or absent cardiac structures, and pericardial fluid can all be distinguished. Studies evaluating the clinical value of three-dimensional echocardiography are ongoing, and its use clinically is still being defined. **Pulsed-wave Doppler** provides a semiquantitative or qualitative estimation of the severity of transvalvular gradients, RV systolic pressure, PA pressure, valvular regurgitation severity, and the presence of intracardiac shunts. The Doppler mitral inflow pattern can help confirm diastolic dysfunction and can help verify a restrictive cardiomyopathic picture or constrictive pericarditis. **Color flow Doppler** provides a visual pattern of blood flow velocities superimposed over the anatomic two-dimensional echocardiographic image. This allows for the demonstration of turbulence from stenotic or regurgitant valves, and for the visualization of intracardiac defects. Since some regurgitant flow occurs normally, especially when the AV valves close, the presence of minor amounts of regurgitant color flow should not be construed as pathology. **Tissue Doppler** methods help define the extent of either mitral annular or ventricular wall motion independent of intracardiac flow velocity, and the relationship between the two may prove useful for defining diastolic pressure elevation, identifying abnormalities in ventricular contraction or diastolic relaxation, or optimizing pacemaker therapy. The E wave of the mitral inflow Doppler pattern reflects the rate of blood flow from the LA to LV. The E' of the tissue Doppler reflects how rapid the LV relaxes. The E/E' ratio increases if the LA pressure pushing blood into the LV is relatively greater than the rate of relaxation. An

E/E' ratio > 15–18, therefore, suggests an elevated LA pressure.

Video

Left ventricular hypertrophy. (Courtesy of B Macrum and E Foster.)

Transesophageal echocardiography (TEE) with Doppler ultrasound is used to obtain echocardiographic data when surface sound transmission is poor; to derive information about posterior structures (especially the atria or atrial appendage and AV valves), prosthetic heart valves, and intracardiac masses not seen on chest wall echocardiography (eg, vegetations in endocarditis or thrombi on pacemaker leads); and to monitor patients during surgery. It can confirm the location of the pulmonary veins and define septal defects or the presence of a patent foramen ovale (PFO). It is superior to surface echocardiography in diagnosing LA appendage thrombi and regurgitant lesions associated with prosthetic valves. It is also quite sensitive in detecting aortic dissection and severe atherosclerosis of the ascending aorta, which may be the source for transient ischemic attacks or embolic strokes (see Video).

Video

Left atrial thrombus. (Courtesy of B Macrum and E Foster.)

Three-dimensional echocardiography is emerging as an outstanding means to visualize cardiac structures in multiple dimensions, though there remains few diagnoses that are only discoverable by three-dimensional echocardiography. Three-dimensional echocardiography technology has been a particularly useful adjunct to transesophageal echocardiography during invasive cardiac procedures and cardiac surgery, where it helps define the relationships among the various heart structures in real time.

Stress echocardiography can be used in valvular as well as ischemic heart disease. Echocardiograms may be performed during or immediately following exercise. Valvular gradient changes after exercise or during dobutamine or nitroprusside infusion can be evaluated. Transient segmental wall motion abnormalities during or immediately following exercise or pharmacologic stress suggest ischemia (see Video). Improvement in wall motion during low-dose dobutamine infusions is an indicator of myocardial viability.

Video

Dobutamine-induced myocardial ischemia. (Courtesy of B Macrum and E Foster.)

Hand held echocardiography has recently been developed that allows for echocardiographic images to be displayed on devices not much larger than a pocket-sized personal digital assistant (PDA). These may evolve into useful tools to document structural heart disease at the bedside.

Cardiac MRI & Multislice CT

Cardiac **MRI** continues to evolve rapidly. Currently available systems provide high-quality and high-resolution images of cardiac and adjacent vascular structures. MRI also provides excellent images that can be used to quantify cardiac function and structure. It is particularly useful for defining infiltrative myocardial diseases such as sarcoidosis or amyloidosis. Flow measurements, valve orifice sizes, and shunt sizes can all be determined. With the use of gadolinium contrast agents, MRI can be used to assess myocardial perfusion during adenosine pharmacologic stress and to assess myocardial viability. Contrast-enhanced images can provide accurate measurement of myocardial infarction size and location. MRI can also provide accurate three-dimensional reconstruction of the great vessels and abdominal aorta. The study can also be used to screen for renal artery stenosis in patients with hypertension. However, patients with pacemakers or defibrillators are not generally believed to be candidates for MRI, though some groups are willing to perform MRI in this situation. Also, a rash (nephrogenic systemic fibrosis) due to the gadolinium contrast agent may develop in patients with severe kidney dysfunction.

Cardiac multislice CT is the newest imaging modality. At lower resolution, it has primarily been used to screen patients for CAD. The extent of calcium within the coronary vessels was found to correlate with the extent of atherosclerotic CAD. More recently, higher resolution imaging modes and faster acquisition have enabled noninvasive coronary angiography to be obtained. The predictive value of a negative coronary study is high (around 95%), suggesting that it is an excellent test to confirm normal coronaries. Calcium in the arterial wall may limit its ability to define the severity of coronary disease, but the inherent resolution of **cardiac multislice CT** allows it to better visualize coronaries than cardiac MRI. Multislice CT, with its impressive three-dimensional reconstruction algorithms, also provides outstanding images in valvular, myocardial, and congenital heart disease. However, there remains some concern regarding the radiation dose with multislice CT, which is not an issue with MRI. For most individuals, however, the effective dose equivalent is around 20 milliSieverts, about the same as a rest and exercise thallium study. Guidelines are currently being developed to better define the role of coronary **multislice CT**.

Cardiac Catheterization & Angiography

Cardiac catheterization is evolving from a diagnostic procedure to a therapeutic one, as more and more types of cardiac lesions are approached with percutaneous techniques.

Right heart catheterization is convenient to perform in the laboratory, at the bedside, or in the operating room. It allows measurement of RA, RV, PA, and pulmonary capillary wedge pressures (PCWP; the latter an indicator of LA pressure), oxygen saturation, and cardiac output (see ECG). These data may diagnose intracardiac shunts, physiologically significant pericardial disease, and right-sided valve lesions and can distinguish between cardiac and pulmonary disease. It is useful in pulmonary hypertension to document whether the elevated pressures are related to pulmonary disease or to left heart disease. In those with pulmonary hypertension, vasodilators can be administered to test for vasoactivity. Hemodynamic monitoring with a PA catheter may be very helpful in the assessment and treatment of shock, heart failure, complicated myocardial infarction, respiratory failure, and postoperative hemodynamic instability. However, this procedure is not without risk—complications include pneumothorax, bleeding, arrhythmias, PA rupture, pulmonary emboli, infection, and patient immobility. Therefore, the role of this procedure remains unsettled, although it is still commonly used to monitor cardiac patients in surgery and in critical care settings. Bedside echocardiography can often fulfill this role for most situations.

Left heart catheterization is performed to assess the cardiac valves and LV function plus the presence and severity of CAD. Valvular stenosis and regurgitation can be semi-quantitated. The ejection fraction (EF) and regional wall motion are assessed by contrast left ventriculography (see x-ray). Stenotic valvular disease is well defined by echocardiography with Doppler ultrasound, but assessing the consequences of regurgitant valvular disease is more difficult and cardiac catheterization with hemodynamics is often more helpful.

Both coronary and noncoronary interventions are now common in the cardiac catheterization laboratory. Acute interventions include plain old balloon angioplasty (POBA) and stenting (now often with stents coated with agents to reduce restenosis). Coronary interventions are now done routinely in the acute as well as chronic setting. Other novel interventional procedures include balloon valvuloplasty (primarily for pulmonic or mitral valve stenosis); stenting of coarctation or branch PA stenosis; percutaneous occlusion of intracardiac defects, such as ASD, PFO or patent ductus arteriosus; or alcohol ablation of the subaortic septum in hypertrophic cardiomyopathy. In addition, percutaneous replacement of the pulmonary and aortic valve is undergoing development, as is research in percutaneous repair of the regurgitant mitral valve.

Congenital Heart Disease: Introduction

Congenital lesions account for only about 2% of heart disease that presents in adulthood. As surgical and medical techniques have improved, more and more children are now reaching adulthood, and it is estimated that there are well over 1 million adults in the United States surviving with congenital heart disease. In fact, there are more adults with congenital heart disease than children. The ACC/AHA has published guidelines for the management of adults with congenital heart disease.

Pulmonary Stenosis

Essentials of Diagnosis

- Asymptomatic unless patient has at least moderately severe lesions.
- Severe cases may present with right-sided heart failure.

- High-pitched systolic ejection murmur maximal in the second left interspace with radiation to the left shoulder.
- P_2 delayed and soft or absent. Ejection click often present and decreases with inspiration—the only right heart auscultatory event that decreases with inspiration, all others increase.
- Increased RV impulse.
- Palpable thrill at second left intercostal space.
- RVH on ECG; PA dilation on radiograph.
- Echocardiography/Doppler is diagnostic.
- Patients with peak pulmonic valve gradients > 60 mm Hg or mean of 40 mm Hg by echocardiography/Doppler should undergo intervention regardless of symptoms.
- A dysplastic pulmonary valve usually requires surgical treatment, while a domed pulmonary valve stenosis usually can be treated with balloon valvuloplasty.

General Considerations

Stenosis of the pulmonary valve or RV infundibulum increases the resistance to RV outflow, raises the RV pressure, and limits pulmonary blood flow (see illustration); (see photograph). Pulmonic stenosis is often associated with other cardiac lesions. Pulmonary blood flow preferentially goes to the left lung in valvular pulmonic stenosis. Most patients with valvular pulmonic stenosis have a domed valve, though some patients have a dysplastic valve, especially those with Noonan syndrome. The phenotype of Noonan syndrome includes short stature, web neck, dental malocclusion, antimongoloid slanting of the eyes, mental retardation, and hypogonadism. Unlike those with a domed valve, patients with a dysplastic valve do not have a dilated main pulmonary artery (PA) or commissural fusion. In the absence of associated shunts, arterial saturation is normal. Infundibular stenosis may be so severe that the right ventricle (RV) is divided into a low-pressure and high-pressure chamber (double-chambered RV). Peripheral pulmonic stenosis can accompany valvular pulmonic stenosis and may be part of a variety of clinical syndromes, including the congenital rubella syndrome. Patients who have had the Ross procedure (transfer of the pulmonary valve to the aortic position with a homograft pulmonary valve placed in the pulmonary position) may experience postoperative pulmonic stenosis due to an immune response in the homograft.

Clinical Findings

Symptoms and Signs

While most of the older data rely on gradients obtained at cardiac catheterization, now the gradients by echo/Doppler are used clinically. Mild PS is present if the peak gradient by echo/Doppler is < 30 mm Hg, moderate PS is present if the peak gradient is between 30 mm Hg and 60 mm Hg, and severe PS is present if the peak gradient is > 60 mm Hg or the mean gradient is > 40 mm Hg. Mild cases of pulmonic stenosis are asymptomatic; moderate to severe pulmonic stenosis may cause symptoms of dyspnea on exertion, syncope, chest pain, and eventually RV failure.

On examination, there is often a palpable parasternal lift due to right ventricular hypertrophy (RVH) and the pulmonary outflow tract may be palpable if it is enlarged. A loud, harsh systolic murmur and occasionally a prominent thrill are present in the left second and third interspaces parasternally. The murmur radiates toward the left shoulder and increases with inspiration . In mild to moderate pulmonic stenosis, a loud ejection click can be heard to precede the murmur; this sound decreases with inspiration as the increased RV filling from inspiration prematurely opens the valve during atrial systole. This is the only right-sided auscultatory event that decreases with inspiration. The valve excursion in systole, therefore, is less with inspiration, and the click diminishes in intensity. The second sound is obscured by the murmur in severe cases; the pulmonary component may be diminished, delayed, or absent. A right-sided S_4 and a prominent *a* wave in the venous pulse are present when there is RV diastolic dysfunction or a *c*-*v* wave if there is tricuspid regurgitation present. Right-sided S_4 gallops may be best heard in the right subclavicular area (where left-sided gallops would be distinctly uncommon). Pulmonic valve regurgitation is relatively uncommon in pulmonic stenosis and may be very difficult to hear, as the gradient between the reduced PA diastolic pressure and the elevated RV diastolic pressure may be quite small (low-pressure pulmonic regurgitation).

Audio
Pulmonary valve stenosis. S1 followed by a click, then a rough systolic murmur and a single S2. The click would disappear with inspiration due to early opening of the pulmonary valve. (Reproduced, with permission, from T. Anthony Don Michael, MD: *Mastering Auscultation* [CD-ROM], 2000.)

ECG and Chest Radiography

Right axis deviation or RVH is noted; peaked P waves provide evidence of right atrial (RA) overload (see ECG). Heart size may be normal on radiographs, or there may be a prominent RV and RA or gross cardiac enlargement, depending upon the severity. There is often poststenotic dilation of the main and left pulmonary arteries (see illustration). The dilatation is primarily due to intrinsic abnormalities of the vessel wall. Pulmonary vascularity is usually normal. A careful look at the chest radiograph may reveal greater vascular perfusion of the left than the right base (Chen sign). Calcium may also be present in the main PA or pulmonic valve.

Fig.
Right atrial and right ventricular hypertrophy. The P waves are abnormally tall in leads II, III, and aVF, indicating right atrial abnormality. The frontal plane QRS axis is oriented rightward (deep S in I) and superiorly (QS complexes in II, III, and aVF); the axis is -110 degrees. A tall R wave is present in V_1. The rightward axis and tall R wave in V_1 indicate right ventricular hypertrophy. In the presence of right ventricular hypertrophy, QS complexes need not indicate myocardial infarction. Diagnostic Studies

Echocardiography/Doppler is the diagnostic tool of choice, can provide evidence for a doming valve versus a dysplastic valve, can determine the gradient across the valve, and can provide information regarding subvalvular obstruction and the presence or absence of tricuspid or pulmonic valvular regurgitation (see Video); (see Video); (see Video). Catheterization is usually unnecessary for the diagnosis (see ECG); it should be used only if the data are unclear or in preparation for either a percutaneous intervention or surgery. MRI and CT do not add additional information unless there is concern regarding associated cardiac lesions or peripheral pulmonary arterial lesions.

Fig.

Pressure tracing showing withdrawal of a catheter across a stenotic pulmonary valve. The pressure gradient across the pulmonary valve is equal to the difference between right ventricular (RV) and pulmonary artery (PA) pressures. Video

Video

Prognosis & Treatment

Patients with mild pulmonic stenosis have a normal life span with no intervention. Moderate stenosis may be asymptomatic in childhood and adolescence, but symptoms often appear as patients grow older. The degree of stenosis does worsen with time in many patients, so serial follow-up is important. Severe stenosis is rarely associated with sudden death but can cause right heart failure in patients as early as in their 20s and 30s. Pregnancy and exercise tends to be well tolerated except in severe stenosis.

Class I indications for intervention include all symptomatic patients and all those with a resting peak gradient over 60 mm Hg or mean > 40 mm Hg, regardless of symptoms. Percutaneous balloon valvuloplasty is highly successful in domed valve patients and is the treatment of choice. Surgical commissurotomy can also be done, or pulmonary valve replacement (with either a bioprosthetic valve or homograft) when pulmonic regurgitation is too severe or the valve is dysplastic. In accordance with the newest guideline recommendations, endocarditis prophylaxis is unnecessary unless there has been prior pulmonary valve endocarditis (a very rare entity).

When to Refer

All symptomatic patients and all asymptomatic patients whose peak gradient is > 60 mm Hg or mean gradient > 40 mm Hg should be referred to a cardiologist with an interest and expertise in adult congenital heart disease.

Coarctation of the Aorta

Essentials of Diagnosis

- Infants may have severe heart failure.
- Usual presentation is systemic hypertension.
- A gradient of > 20 mm Hg by echo/Doppler may be significant.

- Associated bicuspid aortic valve (in 50% of patients).
- Some patients have a webbed neck (XO karyotype, Turner syndrome).
- Absent or weak femoral pulses. Delay of the palpable pulse between the femoral and brachial artery.
- In some patients, the coarctation murmur can be heard in the back. In severe coarctation, the continuous murmurs of collaterals around the coarctation can be heard in the back.
- Systolic pressure is higher in upper extremities than in lower extremities; diastolic pressures are similar.
- ECG shows left ventricular hypertrophy; chest radiograph shows rib notching; echocardiography/Doppler is diagnostic.

General Considerations

Coarctation of the aorta consists of localized narrowing of the aortic arch just distal to the origin of the left subclavian artery. Its development is thought to be related to accessory ductal material that contracts soon after birth. Therefore, it is not usually present in the fetus. Collateral circulation develops around the coarctation through the intercostal arteries and the branches of the subclavian arteries and can lower the transcoarctation gradient. Coarctation is a cause of secondary hypertension and should be considered in young patients with elevated blood pressure (BP). The renin–angiotensin system is reset and this contributes to the hypertension. Elevated BP may not return to normal after coarctation repair. A bicuspid valve is seen in over 50% of the cases, and there is an increased incidence of cerebral berry aneurysms.

Clinical Findings

Symptoms and Signs

If cardiac failure does not occur in infancy, there are usually no symptoms until the hypertension produces left ventricular (LV) failure or cerebral hemorrhage occurs. Strong arterial pulsations are seen in the neck and suprasternal notch. Hypertension is present in the arms, but the pressure is normal or low in the legs. This difference is exaggerated by exercise. Femoral pulsations are weak and are delayed in comparison with the brachial or radial pulse. Patients may have severe coarctation, but with large collaterals may have relatively small gradients because of high flow through the collaterals to the aorta distal to the coarctation. A significant gradient is, therefore, > 20 mm Hg. Late systolic ejection murmurs at the base are often heard better posteriorly, especially over the spinous processes. There may be an associated aortic insufficiency or stenosis murmur due to the bicuspid aortic valve.

ECG and Chest Radiography

The ECG usually shows LV hypertrophy (LVH) (see

ECG). Radiography shows scalloping of the ribs due to enlarged collateral intercostal arteries, dilation of the left subclavian artery and poststenotic aortic dilation, and LV enlargement. The coarctation region and the poststenotic dilation of the descending aorta may result in a "3" sign along aortic shadow on the PA chest radiograph (the notch in the "3" representing the area of coarctation).

Fig.
Left ventricular hypertrophy with left (superior) axis deviation. The mean frontal plane QRS axis is -45 degrees, suggesting the possibility of coexisting left anterior fascicular block. The R wave of 24 mm in aVL, however, strongly suggests (but does not prove) the presence of left ventricular hypertrophy. ST-segment depression and T wave inversion are present in aVL, and T wave inversion is present in V_{4-6}. Precordial lead voltage criteria for left ventricular hypertrophy are not met. This may be due to the superior axis, as a result of which the lead axes of V_{5-6} are far removed from the mean QRS vector. Left ventricular hypertrophy was confirmed at autopsy examination. (Reproduced, with permission, from Goldschlager N, Goldman MJ: *Principles of Clinical Electrocardiography,* 13th ed. Originally published by Appleton & Lange. Copyright ©

1989 by The McGraw-Hill Companies, Inc.)

Diagnostic Studies

Echocardiography/Doppler is usually diagnostic and may provide additional evidence for a bicuspid aortic valve. Both MRI and CT can also provide excellent images of the coarctation local anatomy. MRI and echocardiography/Doppler can also provide estimates of the gradient across the lesion. Cardiac catheterization provides definitive gradient information and is necessary if percutaneous stenting is to be considered.

Prognosis & Treatment

Cardiac failure is common in infancy and in older untreated patients; it is uncommon in late childhood and young adulthood. Patients with a demonstrated gradient of > 20 mm Hg should be considered for intervention. Most untreated patients with the adult form of coarctation die before age 50 years from the complications of hypertension, rupture of the aorta, infective endarteritis, or cerebral hemorrhage. Aortic dissection also occurs with increased frequency. Coarctation of any significance may be poorly tolerated in pregnancy because of the inability to support the placental flow.

Resection of the coarctation site has a surgical mortality rate of 1–4% and includes risk of spinal cord injury. The percutaneous interventional procedure of choice is stenting when anatomically feasible. Otherwise, surgical resection (usually with end-to-end anastomosis) should be performed. About 25% of surgically corrected patients continue to be hypertensive years after surgery because of the changes in the renin–angiotensin system.

When to Refer

All patients should be referred to a cardiologist with an interest in adult congenital heart disease.

Atrial Septal Defect & Patent Foramen Ovale

Essentials of Diagnosis

- Often asymptomatic and discovered on routine physical examination.
- RV lift; S_2 widely split and fixed.
- Grade I–III/VI systolic ejection murmur at

pulmonary area.

- ECG shows RV conduction delay; radiograph shows dilated pulmonary arteries and increased vascularity.
- All atrial septal defects should be closed either by a percutaneous device or by surgery if there is any evidence of an RV volume overload regardless of symptoms.
- Echocardiography/Doppler is diagnostic.
- A patent foramen ovale is present in 25% of the population but can lead to paradoxic emboli and cerebrovascular events. Suspicion should be highest in patients who have cryptogenic stroke before age 55 years.

General Considerations

Knowing how the atrial septum forms helps in understanding the different anatomic lesions that create a communication between the atria (eFigure 10–1.0: illustration). Embryologically, the septum primum separates the two atria, first moving inferiorly toward the endocardial cushions. The ventricular septum forms by moving upward from the ventricles to the endocardial cushions at the same time. If the atrial septum does not make it all the way, the residual defect in the septum primum (ostium primum) results in the **primum ASD**. If the septum primum makes it all the way, a hole or holes (fenestrations) form in the middle of the septum (forming the ostium secundum). A second septum then moves down the right side of the first and normally covers the ostium secundum hole. If it does not cover the hole, a **secundum ASD** is present. The septum secundum normally completely covers the right side of the atrial septum except for an ovale hole in it inferiorly (the foramen ovale). If the septae do not fuse, a patent path from the RA to the LA persists (the PFO). The most common form of atrial septal defect (ASD) (80% of cases) is persistence of the ostium secundum in the mid septum; less common is the persistence of the ostium primum (low in the septum). In many patients with an ostium primum defect, there are mitral or tricuspid valve clefts as well as a ventricular septal defect (VSD) as part of the atrioventricular (AV) canal defect (see illustration). A third form of ASD is the **sinus venosus defect,** a hole usually at of the upper part of the atrial septum due to failure of the embryonic superior vena cava (SVC) or the inferior vena cava (IVC) to merge with the atria properly. The IVC sinus venosus defect is very rare. The SVC sinus venosus is often associated with anomalous drainage of the right upper pulmonary vein into the SVC. A very uncommon form of ASD is the **coronary sinus ASD** that is basically an unroofed coronary sinus. In all cases, normally oxygenated blood from the higher-pressure LA passes into the RA, increasing RV output and pulmonary blood flow. In children, the degree of shunting across these defects may be quite large (3:1 or so). As the RV diastolic pressure rises from the chronic volume overload, the RA pressure may rise and the degree of left-to-right shunting may decrease. Eventually, if the RA pressure exceeds the LA, the shunt may be right-to-left and cyanosis appears.

eFigure 10–1.0.

Atrial septal anatomy. **A:** Embryologically, the septum primum (first septum) divides the atrium by migrating to the ventricles. The gap preceding the septal migration is the ostium primum. **B:** Once the septum primum completes its journey, fenestrations (holes) appear and generally coalesce into a single ostium secundum. **C:** A second septum (septum secundum) grows down on the right atrial side of the septum primum and covers the entire septal area except for a large oval hole that forms in its distal portion (the foramen ovale). **D:** If there is redundancy of either the septum primum (as shown) or both septae, then that defines a septal aneurysm.

Fig.

Anatomic features of atrial septal defect. (Reproduced, with permission, from Cheitlin MD, Sokolow M, McIlroy MB: *Clinical Cardiology*, 6th ed. Originally published by Appleton & Lange. Copyright © 1993 by The McGraw-Hill Companies, Inc.)

The pulmonary pressures are modestly elevated in most patients with an ASD due to the high pulmonary blood flow, but severe pulmonary hypertension with cyanosis (Eisenmenger physiology) is actually unusual, occurring in only about 15% of the patients with an ASD alone (see illustration). Eventual RV failure may occur though, and most shunts should be corrected unless they are quite small (< 1.5:1 right-to-left shunt). In adults, a large right-to-left shunt may have begun to reverse, so the absolute left-to-right shunt measurement (Qp/Qs, where Qp=pulmonary flow and Qs=systemic flow) at the time the patient is studied may underestimate what it was some years ago. In addition, in most patients the LV compliance normally declines more over time than the RV, and the natural history of small atrial septal shunts is to increase as the patient ages (unless RV failure ensues) as the LA compliance worsens more than the RA.

Fig.

Eisenmenger's syndrome. Structures enlarged: right ventricle, right atrium, and pulmonary artery. (Reproduced, with permission, from Cheitlin MD, Sokolow M, McIlroy MB: *Clinical Cardiology*, 6th ed. Originally published by Appleton & Lange. Copyright © 1993 by The McGraw-Hill Companies, Inc.)

ASDs predispose to atrial fibrillation due to RA enlargement, and paradoxic right-to-left emboli do occur. Interestingly, paradoxic emboli may be more common in patients with a patent foramen ovale (PFO) than a true ASD, as the eustachian valve in the RA directs flow from the IVC toward the septum, and the usual significant left-to-right flow from an ASD is often not present with a simple PFO. An **aneurysm of the atrial septum** is when there is redundancy of the septum primum through the foramen ovale, although it may include redundancy of the septum secundum as well. When present with a PFO, there is more shunting right to left as the atrial septum swings back and forth. This latter anatomic issue may explain why more right to left shunting occurs in patients with an atrial septal aneurysm and PFO than in those with a PFO alone.

Clinical Findings

Symptoms and Signs

Patients with small or moderate ASDs or with a PFO are asymptomatic unless a complication occurs. With large shunts, exertional dyspnea or cardiac failure may develop, most commonly in the fourth decade of life or later. Prominent RV and PA pulsations are readily visible and palpable. A moderately loud systolic ejection murmur can be heard in the second and third interspaces parasternally as a result of increased PA flow. S_2 is widely split and does not vary with breathing due to the fact that the left-to-right shunt decreases as the RA pressure increases with inspiration . In very large left-to-right shunts, a tricuspid rumble may be heard due to the high flow.

ECG and Chest Radiography

Right axis deviation or RVH may be present depending on the size of the RV volume overload (see ECG); (see ECG). Incomplete or complete right bundle branch block is present in nearly all cases of ASD, and superior axis deviation is noted in the AV canal defect, where complete heart block is often seen as well. With sinus venosus defects, the P axis is leftward of +15° due to abnormal atrial activation with loss of the upper RA tissue from around the sinus node. The chest radiograph shows large pulmonary arteries, increased pulmonary vascularity, an enlarged RA and RV, and a small aortic knob (see x-ray) with all pre-tricuspid valve cardiac left-to-right shunts.

Fig.

Right bundle branch block pattern with upright T waves in $V_{2\text{-}3}$ and diphasic T waves in V_1. Deep, wide Q waves in leads II, III, and aVF indicate inferior wall myocardial infarction (old, suggested by the upright T waves in these leads), and the notched R wave in lead V_1 indicates posterior wall infarction. The upright T waves in the leads reflecting the right intraventricular conduction delay are not expected and are termed *primary* T wave abnormalities. While primary T wave abnormalities are not specific for the diagnosis of ischemic heart disease, this should be considered. In this patient, the occurrence of the inferior wall myocardial infarction was associated with the change from the expected secondary ST depression and T wave inversion in V_1-3 to this primary pattern. Atrial septal defect of ostium secundum type. (Courtesy of H Goldberg.)

Diagnostic Studies

Echocardiography demonstrates evidence of RA and RV volume overload. The atrial defect is usually observed, though sinus venosus defects may be elusive. Many patients with a PFO also have an atrial septal aneurysm. Echocardiography with agitated saline bubble contrast can demonstrate a right-to-left shunt and both pulsed and color flow Doppler flow studies can demonstrate shunting in either direction (see Video). A transesophageal echocardiogram (TEE) is helpful when transthoracic echocardiography quality is not optimal, and it improves the sensitivity for small shunts and provides a better assessment of PFO anatomy. Radionuclide flow studies quantify left-to-right shunting by observing the bolus of contrast within the lung fields and demonstrating early recirculation. Both CT and MRI can elucidate the atrial septal anatomy and demonstrate associated lesions. Cardiac catheterization is often helpful, especially if there are associated anomalous pulmonary veins. The size and location of the shunt can be determined and the pulmonary pressure and pulmonary vascular resistance (PVR) measured (see ECG). Cardiac catheterization is required if percutaneous closure is to be contemplated.

Fig.

Simultaneous left and right atrial and differential pressure across an atrial septal defect. The pressure difference across the defect is greatest before the *v* wave. The right atrial pressure tracing is inverted because it is recorded by a differential manometer. (Reproduced, with permission, from Cheitlin MD, Sokolow M, McIlroy MB: *Clinical Cardiology*, 6th ed. Video

Atrial septal defect with right-to-left shunting. (Courtesy of B Macrum and E Foster.)

Prognosis & Treatment

Patients with small atrial shunts may live a normal life span. Large shunts usually cause disability by age 40 years. Because left-to-right shunts tend to increase with age-related changes in LV compliance, most clinicians believe that closure of all left-to-right shunts over 1.5:1 should be accomplished. This situation always results in RV volume overload. Current guidelines suggest that all ASDs should be closed if there is evidence of RV volume overload on echocardiogram. Increased PVR and hypertension secondary to pulmonary vascular disease rarely occur in childhood or young adult life in secundum defects but are more common in primum defects. After age 40 years, cardiac arrhythmias (especially atrial fibrillation) and heart failure may occur due to the chronic right heart volume overload. Paradoxical systemic arterial embolization becomes more of a concern as RV compliance is lost and the left-to-right shunt begins to reverse.

PFOs are not associated with significant shunting, and therefore the patients are asymptomatic and the heart size is normal. However, PFOs are responsible for most paradoxical emboli and are one of the most frequent causes of cryptogenic strokes in patients under age 55 years.

Small ASDs do not require intervention if echocardiography shows that the shunt is not creating an RV volume overload. Surgery involves anything from simple stitching of the foramen closed to patching of the hole with Dacron or a pericardial patch. Anomalous pulmonary venous connections are baffled to the LA through the sinus venosus defect when such anomalous veins are present. For ostium secundum ASDs, percutaneous closure by use of a variety of devices is now preferred over surgery. The percutaneous closure devices often resemble double umbrellas that lock the septum between the Dacron umbrellas when opened, though many designs are becoming available.

Patients with a PFO who have symptoms related to stroke or transient ischemic attack (especially if the age is under 55) or who have hypoxemia (especially upon standing—so called platypnea orthodeoxia) should probably have the PFO closed if no other cause for symptoms is evident. Migraine headaches may be more common in patients with a PFO, suggesting some unknown substance normally metabolized in the lung is entering the systemic circulation through the PFO, but current data remain unclear in this regard. For patients with cryptogenic stroke or transient ischemic attack, it is uncertain whether closure of the PFO, either by open surgical or percutaneous techniques, has any advantage over anticoagulation with either warfarin or aspirin. Although there are no data yet suggesting that PFO closure is better than medical therapy, ongoing randomized trials will help settle this issue.

When to Refer

- All patients with an ASD initially discovered at echo/Doppler should be evaluated by a cardiologist with expertise in adult congenital disease to ensure no other structural disease is present.

- If the RA and RV sizes remain normal, serial echocardiography (yearly) should be performed.
- If the RA and RV volumes increase, then referral to a cardiologist who performs percutaneous closure is warranted.

Ventricular Septal Defect

Essentials of Diagnosis

- A restrictive VSD is small and makes a louder murmur than an unrestricted one.
- Small defects may be asymptomatic.

- Larger defects may result in pulmonary hypertension (Eisenmenger physiology) if not repaired.
- A grade II–VI/VI pansystolic murmur maximal at the left sternal border is heard; an associated thrill is common.
- ECG may show LVH, RVH, or both; radiograph shows increased pulmonary vascularity, and increased PA and LA size.
- Echocardiography/Doppler is diagnostic.The higher the gradient across the septum, the smaller the left-to-right shunt.

General Considerations

De novo VSDs are uncommon in adults. Congenital VSDs occur in various parts of the ventricular septum. Four types are often described: in **type A,** the VSD lies underneath the semilunar valves; in **type B,** the VSD is membranous with three variations; in **type C,** the inlet VSD is present below the tricuspid valve and often part of the AV canal defect; and **type D** is the muscular VSD (see illustration). Membranous and muscular septal defects may spontaneously close in childhood as the septum grows and hypertrophies. A left-to-right shunt is present unless there is associated RV hypertension. The smaller the defect, the greater the gradient from the LV to the RV and the louder the murmur. The presentation in adults is dependent on the size of the shunt and whether there is associated pulmonic or subpulmonic stenosis that has protected the lung from the systemic pressure and volume. Unprotected lungs with large shunts invariably lead to pulmonary vascular disease and severe pulmonary hypertension (Eisenmenger physiology).

Fig.

Anatomic location of ventricular septal defects. (Reproduced, with permission, from Way LW [editor]: *Current Surgical Diagnosis & Treatment*, 10th ed. Originally published by Appleton & Lange. Copyright © 1994 by The McGraw-Hill Companies, Inc.)

Clinical Findings

Symptoms and Signs

The clinical features depend on the size of the defect and the presence or absence of RV outflow obstruction or an increased PVR. Small shunts are associated with loud, harsh holosystolic murmurs in the left third and fourth interspaces along the sternum . Larger shunts may create RV volume and pressure overload. If pulmonary hypertension occurs, high-pressure pulmonic regurgitation may result. A systolic thrill is common. Right heart failure may gradually become evident late in the course, and the shunt will begin to reverse as RV and LV systolic pressures equalize with the advent of pulmonary hypertension. Cyanosis from right-to-left shunting may then occur.

ECG and Chest Radiography

The ECG may be normal or may show right, left, or biventricular hypertrophy (see ECG), depending on the size of the defect and the PVR. With large shunts, the RV, the LV the LA, and the pulmonary arteries are enlarged, and pulmonary vascularity is increased on chest radiographs. If PVR (pulmonary hypertension) evolves, an enlarged PA with pruning of the distal pulmonary vascular bed is seen. In rare cases of a VSD high in the ventricular septum, an aortic cusp may prolapse into the VSD and reduce the VSD shunt but result in acute aortic regurgitation.

Fig.

Combined right and left ventricular hypertrophy. The mean frontal plane QRS axis is +105 degrees. ST-segment depression is present in leads II, III, aVF, and V_6. SV_1 $RV_5 = 39$ mm. The combination of right axis deviation and precordial lead voltage criteria for left ventricular hypertrophy is a reliable indicator of biventricular hypertrophy. (Reproduced, with permission, from Goldschlager N, Goldman MJ: *Principles of Clinical Electrocardiography*, 13th ed. Originally published by Appleton & Lange. Diagnostic Studies

Echocardiography can demonstrate the size of the overloaded chambers and can usually define the defect anatomy. Doppler can qualitatively assess the magnitude of shunting by noting the gradient from LV to RV and, if some tricuspid regurgitation is present, the RV systolic pressure can be estimated (see Video). Color flow Doppler helps delineate the shunt defect and the presence of valvular regurgitation. MRI and cardiac CT can often visualize the defect and describe any other anatomic abnormalities. MRI can provide quantitative shunt data as well. Radionuclide flow studies are sometimes used to quantify the relative size of the left-to-right shunt. Cardiac catheterization is usually reserved for those with at least moderate shunting to determine the PVR and the degree of pulmonary hypertension. A PVR of > 7.0 absolute units or a PVR/systemic vascular resistance (SVR) ratio of greater than 0.67 (two-thirds systemic) usually implies inoperability.

Video
Ventricular septal defect. (Courtesy of B Macrum and E Foster.)

Prognosis & Treatment

Patients with the typical murmur as the only abnormality have a normal life expectancy except for the threat of infective endocarditis. Endocarditis is more typical of smaller shunts due to the high velocity of the jet lesion damaging the tricuspid septal leaflet or RV free wall. Antibiotic prophylaxis is still recommended. With large shunts, CHF may develop early in life, and survival beyond age 40 years is unusual without intervention.

The newest guidelines for the management of patients with VSD include the following:

1. Medical management (class 2b recommendation): Pulmonary vasodilatory therapy is appropriate for adults with a VSD and severe pulmonary hypertension.

2. Surgical management (class 1 recommendation): Closure is indicated when the left-to-right shunt ratio is > 2.0 or there is clinical LV volume overload. In addition, closure is recommended if there has been a history of infective endocarditis.

3. Surgical management (class 2b recommendation): Closure is reasonable if the left-to-right shunt is > 1.5 and pulmonary pressure and PVR are less than two-thirds systemic pressure and SVR. Closure is also reasonable if the shunt ratio is > 1.5 and there is evidence for heart failure.

Small shunts (pulmonary-to-systemic flow ratio < 1.5) in asymptomatic patients do not require surgery or other intervention. Defects causing large shunts should be repaired to prevent pulmonary hypertension or late heart failure. The presence of RV infundibular stenosis distal or pulmonary valve stenosis may protect the pulmonary circuit such that some patients even with a large VSD may still be operable as adults.

Surgical repair of a VSD is generally a low risk procedure unless there is significant Eisenmenger physiology. Currently, several new percutaneous closure devices are under investigation for nonsurgical closure of VSDs. Devices for muscular VSDs are approved and those for membranous VSDs are being implanted with promising results. The device is also approved for closure of a VSD related to acute myocardial infarction, although the results in this very high-risk patient population have not been great to date.

When to Refer

All patients with a VSD should be referred to a cardiologist with expertise in adult congenital disease initially to decide if long-term follow-up is warranted.

Fu YC et al. Transcatheter closure of perimembranous ventricular septal defects using the new Amplatzer membranous VSD occluder: results of the U.S. phase I trial. J Am Coll Cardiol. 2006 Jan 17;47(2):319–25. [PMID: 16412854]

Tetralogy of Fallot

Essentials of Diagnosis

- Four features are characteristic:
  - VSD.
  - RVH.
  - RV outflow obstruction from infundibular stenosis.
  - Overriding aorta (< 50%); a right-sided aortic arch is seen in 25%.
- Most adult patients with tetralogy of Fallot have been operated upon, usually with an RV outflow patch and

VSD closure.

- Physical examination may be deceptive after classic tetralogy repair, with wide-open pulmonic regurgitation often present if a transannular patch was used.
- Echocardiography/Doppler may underestimate significant pulmonic regurgitation. Be wary if the RV is enlarged.
- Arrhythmias are common and periodic Holter monitoring is recommended.
- If the QRS width is > 180 msec, then the patient is subject to serious arrhythmias and sudden death.

General Considerations

Patients with tetralogy of Fallot have a VSD, RV infundibular stenosis, RVH, and a dilated aorta (in about 50% of patients it overrides the septum). There may or may not be pulmonary valve stenosis as well, usually due to a bicuspid pulmonary valve. The aorta can be quite enlarged and aortic regurgitation may occur. If more than 50% of the aorta overrides into the RV outflow tract, the situation is not unlike a double outlet RV. Two vascular abnormalities are common: a right-sided aortic arch (in 25%) and anomalous left anterior descending coronary artery from the right cusp. The latter is important in that surgical correction must avoid cutting this vessel when repairing the RV outflow obstruction and producing an anterior myocardial infarction.

Most adult patients have undergone prior surgery. If significant RV outflow obstruction is present in infancy, a Blalock-Taussig (or similar) shunt is often the initial surgical procedure to improve pulmonary blood flow. This procedure enables blood to reach the underperfused lung either by directly attaching one of the subclavian arteries to the PA (**classic Blalock shunt**) or by creating a conduit between the two (**modified Blalock shunt**). Other types of systemic to pulmonary shunts no longer in use include a window between the right PA and the aorta (**Waterston-Cooley shunt**) or a window between the left PA and the descending aorta (**Potts shunt**). In the adult, there may be a reduced upper extremity pulse on the side used for the Blalock procedure. **Total repair** of the tetralogy of Fallot generally includes a VSD patch and usually an enlarging RV outflow tract patch, as well as a take-down of the Blalock shunt. Often the RV outflow tract patch extends through the pulmonary valve into the PA (transannular patch), and the patient is left with wide-open pulmonic regurgitation. Over the years, the volume overload from the severe pulmonary regurgitation becomes the major hemodynamic problem. Ventricular arrhythmias can also originate from the edge of the patch, and tend to correlate with the size of the RV.

Clinical Findings

Most patients are relatively asymptomatic unless right heart failure occurs or arrhythmias become an issue. Patients can be active and generally require no specific therapy except endocarditis prophylaxis.

Symptoms and Signs

Physical examination should include checking both arms for any loss of pulse from a prior shunt procedure in infancy. The jugular venous pulsations (JVP) may reveal an increased *a* wave from poor RV compliance or rarely a *c*-*v* wave due to tricuspid regurgitation. The right-sided arch has no consequence. The precordium may be active, often with a persistent pulmonary outflow murmur. P_2 may or may not be present. A right-sided gallop may be heard. A residual VSD or aortic regurgitation may also be present. At times, the insertion site of a prior Blalock or other shunt may create a stenotic area in the PA and a continuous murmur occurs as a result.

ECG and Chest Radiography

The ECG reveals RVH and right axis deviation; in repaired tetralogy, there is often a right bundle branch block pattern. The chest radiograph shows a classic boot-shaped heart with prominence of the RV and a concavity in the RV outflow tract. This may be less impressive following repair. The aorta may be enlarged and right-sided. Importantly, the width of the QRS should be examined yearly. There are data that persons at greatest risk for sudden death are those with a QRS width of greater than 180 msec. The width of the QRS corresponds to the RV size, and in many patients, the QRS width actually decreases following repair of the pulmonary insufficiency.

Diagnostic Studies

Echocardiography/Doppler usually establishes the diagnosis by noting the unrestricted (large) VSD, the RV infundibular stenosis, and the enlarged aorta. In patients who have had tetralogy of Fallot repaired, echocardiography/Doppler also provides data regarding the amount of pulmonic regurgitation, RV and LV function, and the presence of aortic regurgitation.

Cardiac MRI and CT can quantitate both the pulmonary insufficiency and the RV volumes. In addition, cardiac MRI and CT can identify whether there is either a native pulmonary arterial branch stenosis or a stenosis at the distal site of a prior Blalock or other shunt. Cardiac catheterization is sometimes required to document the degree of pulmonic regurgitation because noninvasive studies depend on velocity gradients. Pulmonary angiography demonstrates the degree of pulmonic regurgitation, and RV angiography helps assess any postoperative outflow tract aneurysm.

Prognosis & Treatment

A few patients with "just the right amount" of pulmonic stenosis enter adulthood without having had surgery. However, most patients have had surgical repair of tetralogy of Fallot, including VSD closure, resection of infundibular muscle, and insertion of an outflow tract patch. Many have a transannular patch resulting in pulmonic regurgitation. Patients should be monitored to ensure the RV volume does not increase. Low-pressure pulmonic regurgitation is difficult to diagnose except during cardiac catheterization due to the fact that the RV diastolic pressures tend to be high and the pulmonary arterial diastolic pressure is low. This means there is little gradient between the PA and the RV in diastole, so that there may be little murmur or evidence for turbulence on color flow Doppler. If the RV begins to enlarge, it must be assumed that this is due to pulmonic regurgitation until proven otherwise.

If an anomalous coronary is present, then an extracardiac conduit around it from the RV to the PA may be necessary. By 20-year follow-up, reoperation is needed in about 10–15%, not only for severe pulmonic regurgitation but also for residual infundibular stenosis. Usually the pulmonary valve is replaced with a pulmonary homograft, though a porcine bioprosthetic valve is also suitable. Cryoablation of tissue giving rise to arrhythmias is sometimes performed at the time of reoperation. Branch pulmonary stenosis may be percutaneously opened by stenting. All patients require endocarditis prophylaxis. Most adults with stable hemodynamics can be quite active, and most women can carry a pregnancy adequately.

When to Refer

All patients with tetralogy of Fallot should be referred to a cardiologist with expertise in adult congenital heart disease.

Bashore TM. Adult congenital heart disease: Right ventricular outflow tract lesions. Circulation. 2007 Apr 10;115(14):1933–47. [PMID: 17420363]

Patent Ductus Arteriosus

Essentials of Diagnosis

- Rare in adults.
- Adults with small or moderate size patent ductus arteriosus are usually asymptomatic, at least until middle age.
- Widened pulse pressure; loud S_2.
- Continuous murmur over left pulmonary area; thrill common.
- Echocardiography/Doppler is helpful, but the lesion is best visualized by MRI, CT, or contrast

angiography.

General Considerations

The embryonic ductus arteriosus allows shunting of blood from the PA to the aorta in utero. The ductus arteriosus normally closes immediately after birth so that pulmonary blood flows to the pulmonary arteries. Failure to close normally results in a persistent shunt connecting the left PA and aorta, usually near the origin of the left subclavian artery. Prior to birth, the ductus is kept patent by the effect of circulating prostaglandins; in the neonate, a patent ductus can often be closed by administration of a prostaglandin inhibitor such as indomethacin. The effect of the persistent left-to-right shunt on the pulmonary circuit is dependent on the size of the ductus. If large enough, pulmonary hypertension (Eisenmenger physiology) may occur (see illustration). A small ductus may be well tolerated until adulthood.

Clinical Findings

Symptoms and Signs

There are no symptoms unless LV failure or pulmonary hypertension develops. The heart is of normal size or slightly enlarged, with a hyperdynamic apical impulse. The pulse pressure is wide, and diastolic pressure is low. A continuous rough "machinery" murmur, accentuated in late systole at the time of S_2, is heard best in the left first and second interspaces at the left sternal border . Thrills are common. If pulmonary hypertension is present (Eisenmenger physiology), the shunt may reverse and the lower body receives desaturated blood, while the upper body receives saturated blood. Thus, the hands appear normal while the toes are cyanotic and clubbed.

Audio
Patent ductus arteriosus (PDA). Continuous murmur. S2 is obliterated by the waxing and waning of the murmur. (Reproduced, with permission, from T. Anthony Don Michael, MD: *Mastering Auscultation* [CD-ROM], 2000.)

ECG and Chest Radiography

A normal tracing or LVH is found, depending on the magnitude of shunting (see ECG). On chest radiographs, the heart is normal in size and contour, or there may be LV and LA enlargement. The PA, aorta, and LA are prominent because they all are in the shunt pathway.

Fig.
Left ventricular hypertrophy. The mean frontal plane

QRS axis is -15 degrees. The R wave exceeds 15 mm in aVL, and the sum of the S wave in V_1 and the R wave in V_5 exceeds 35 mm. ST-segment depression is present in leads I and aVL, and T wave inversion is present in I, aVL, and V_{5-6}. The deep S waves in the right precordial leads reflect the large electrical force generated by the hypertrophied left ventricle. The ST-segment elevation in V_{1-2} is consistent with left ventricular hypertrophy. (Reproduced, with permission, from Goldschlager N, Goldman MJ: *Principles of Clinical Electrocardiography*, 13th ed. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Diagnostic Studies

Echocardiography/Doppler can determine LV, RV, and atrial dimensions. Color flow Doppler allows visualization of the high velocity shunt jet into the proximal left PA. Cardiac MRI and CT can demonstrate the abnormality and assess the size of the pulmonary arteries. Cardiac catheterization can establish the shunt size and direction, and define the size and anatomic features of the ductus. It can also help determine whether pulmonary hypertension has occurred. If percutaneous closure is feasible, catheterization can be therapeutic.

Prognosis & Treatment

Large shunts cause a high mortality rate from cardiac failure early in life. Smaller shunts are compatible with long survival, CHF being the most common complication (see photograph). Infective endocarditis or endarteritis may also occur, and antibiotic prophylaxis is recommended.

Fig.

Hands and feet of a 30-year-old woman with a patent ductus arteriosus and severe pulmonary vascular disease resulting in a large right-to-left shunt through the ductus. Note clubbed, cyanotic toes and pink, normal fingers. (Reproduced, with permission, from Cheitlin MD, Sokolow M, McIlroy MB: *Clinical Cardiology*, 6th ed. Originally published by Appleton & Lange. Copyright © 1993 by The McGraw-Hill Companies, Inc.)

Surgical ligation of the patent ductus can be accomplished with excellent results. If the ductus has a "neck" and is of small enough size, percutaneous approaches using either coils or occluder devices are the preferred therapy. Newer duct occluder devices have a high success rate at a very low risk.

Table 10–1 outlines the new recommendations for intervention in patients with a patent ductus arteriosus.

Table 10–1. Recommendations for interventions in patients with patent ductus arteriosus.[1]
Class I
A. Closure of a patent ductus arteriosus either percutaneously or surgically is indicated for the following:
1. Presence of left atrial or left ventricular enlargement, pulmonary artery hypertension, or net left-to-right shunting (level of evidence: C)
2. Prior endarteritis (level of evidence: C)
B. Consultation with adult congenital heart disease interventional cardiologists is recommended before surgical closure is selected as the method of repair for patients with a calcified patent ductus arteriosus (level of evidence: C).
C. Surgical repair by a surgeon experienced in coronary heart disease surgery is recommended when:
1. The patent ductus arteriosus is too large for device closure (level of evidence: C).
2. Distorted ductal anatomy precludes device closure (eg, aneurysm or endarteritis) (level of evidence: B).
Class IIa

A. It is reasonable to close an asymptomatic small patent ductus arteriosus by catheter device (level of evidence: C).
B. Patent ductus arteriosus closure is reasonable for patients with pulmonary artery hypertension with a net left-to-right shunt (level of evidence: C).
Class III
Patent ductus arteriosus closure is not indicated for patients with pulmonary artery hypertension and net right-to-left shunt (level of evidence: C).

[1] Class I indicates treatment is useful and effective, IIa indicates weight of evidence is in favor of usefulness/efficacy, class IIb indicates weight of evidence is less well established, and class III indicates intervention is not useful/effective and may be harmful. Type A recommendations are derived from large-scale randomized trials, and B recommendations are derived from smaller randomized trials or carefully conducted observational analyses. ACC/AHA, American College of Cardiology/American Heart Association.

When to Refer

All patients with PDA should be referred to a cardiologist with expertise in adult congenital disease.

Masura J et al. Long term outcome of transcatheter patent ductus arteriosus closure using Amplatzer patent ductus occluders. Am Heart J. 2006 Mar;151(3):755. [PMID: 16504649]

Warnes CA et al. ACC/AHA 2008 Guidelines for the Management of Adults With Congenital Heart Disease. A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. Circulation. 2008 Dec 2;118(23):e714–833. [PMID: 18997169]

Valvular Heart Disease: Introduction

At one time, most cases of valvular disease in the United States were due to rheumatic heart disease (still true in developing countries), other causes are now much more common. In the elderly, "degenerative" calcific aortic valvular disease is now believed due to the same process that produces atherosclerosis, and studies have suggested that about 25% of adults over age 65 have some thickening of their aortic valve (aortic sclerosis) while 2–3% have frank aortic stenosis (see x-ray; x-ray; ECG). Aortic sclerosis alone is a marker for future cardiovascular events and death. Calcium deposition may also occur in the mitral annulus creating enough dysfunction of the valve that either stenosis or regurgitation (or both) results. There is also increasing information that genetic markers associated with aortic stenosis may play a role in the expression of the disease. Mitral valve prolapse is still frequently seen and may be associated with the hyperadrenergic syndrome in younger patients. Valvular regurgitation may be due to LV dysfunction (mitral regurgitation) or RV dysfunction (tricuspid regurgitation).

Fig.
Serial chest radiographs of a patient with aortic stenosis taken 10 years apart. The left ventricle (LV) and aorta (AO) are prominent in both radiographs. The heart is larger and the right hilar vessels more prominent in the film at the bottom, which was taken after the development of symptoms. (Reproduced, with permission, from Cheitlin MD, Sokolow M, McIlroy MB: *Clinical Cardiology*, 6th ed. Originally published by Appleton & Lange. Copyright © 1993 by The McGraw-Hill Companies, Inc.)

Fig.

Echocardiography yields key information about valve morphology, LV mass and function, and atrial and ventricular chamber size. Doppler ultrasound provides quantitative measurements of transvalvular gradients and RV systolic pressure (a surrogate for peak PA pressure when there is no pulmonic stenosis) and gives more qualitative estimates of the presence and severity of valvular regurgitation. TEE often provides improved image quality and valve morphology (particularly prosthetic valves), vegetations, thrombi, and eccentric regurgitant jets are more easily identified with TEE. Cardiac MRI and CT generally add only confirmatory information, though abnormalities of the great vessels are best seen by these modalities; the procedures are useful in tracking the size of ascending aortic aneurysms in patients with bicuspid aortic valve and in quantitating RV function.

Mitral Stenosis

Essentials of Diagnosis

- Exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea when the stenosis becomes severe.
- Symptoms often precipitated by onset of atrial fibrillation or pregnancy.
- Two syndromes occur; one with moderate mitral stenosis and pulmonary edema, and one with severe mitral stenosis, pulmonary hypertension, and low cardiac output.
- Prominent mitral first sound, opening snap (usually), and apical diastolic rumble.

- ECG shows LA abnormality and, commonly, atrial fibrillation.
- Echocardiography/Doppler is diagnostic.
- Surgery indicated for symptoms or evidence of pulmonary hypertension. Most symptomatic patients have a valve area less than 1.5 cm^2.

General Considerations

Patients with mitral stenosis are usually presumed to have underlying rheumatic heart disease, though a history of rheumatic fever is usually noted in only about one-third. Rheumatic mitral stenosis results in thickening of the leaflets, fusion of the mitral commissures, retraction, thickening and fusion of the chordae, and calcium deposition in the valve. Mitral stenosis can also occur due to congenital disease with chordal fusion or papillary muscle malposition. The papillary muscles may be abnormally close together, sometimes so close they merge into a single papillary muscle (the parachute mitral valve). In these patients, the chordae and/or valvular tissue may also be fused. In other patients, mitral annular calcification may build up enough to produce a mitral gradient, most often in the elderly or patients with end-stage renal disease. Calcium in the mitral annulus virtually invades the mitral leaflet from the annulus inward. Mitral valve obstruction may also develop in patients who have had mitral valve repair with a ring that is too small, or in patients who have had a surgical valve replacement. (See x-ray; x-ray.)

Clinical Findings

Symptoms and Signs

A characteristic finding of rheumatic mitral stenosis is an opening snap following S_2 due to the stiff mitral valve . The interval between the opening snap and aortic closure sound is long when the LA pressure is low but shortens as the LA pressure rises and approaches the aortic diastolic pressure. As mitral stenosis worsens, there is a localized diastolic murmur low in pitch whose duration increases with the severity of the stenosis, and the heart murmur is best heard at the apex with the patient in the left lateral position (Table 10–2). Brief exercise, such as sit ups, increase the heart rate and cardiac output resulting in increased flow across the mitral valve and increased audibility of the mitral rumble. Mitral regurgitation may accompany mitral stenosis. Generally, if a regurgitant murmur is audible, there is too much mitral regurgitation to allow either percutaneous valvuloplasty or surgical commissurotomy and valve replacement is the only alternative when appropriate. (see x-ray.)

Fig.

A: Mitral regurgitation. On chest radiograph, the left atrium is enlarged–seen here as an extra density behind the heart. In addition, there is enlargement of the main pulmonary artery. This produces an additional projection above the left ventricular contour. ***B:*** This lateral film demonstrates a prosthetic mitral valve, which in this patient is insufficient. The left atrium is enlarged, pressing against the left main stem bronchus. In addition, the retrosternal space is filled in, typical of enlargement of the pulmonary artery and right ventricle. (Courtesy of H Goldberg.)

Two clinical syndromes occur with mitral stenosis. In **mild to moderate mitral stenosis,** LA pressure and cardiac output may be essentially normal, and the patient is either asymptomatic or symptomatic only with extreme exertion. The measured valve area is usually between 1.8 cm^2 and 1.3 cm^2. In **severe mitral stenosis** (valve area < 1.0 cm^2), severe pulmonary hypertension develops due to a "secondary stenosis" of the pulmonary vasculature. In this condition, pulmonary edema is uncommon, but symptoms of low cardiac output and right heart failure predominate.

Paroxysmal or chronic atrial fibrillation develops in 50–80% of patients. Any increase in the heart rate reduces diastolic time and increases the mitral gradient. A sudden increase in heart rate may precipitate pulmonary edema. Therefore, heart rate control is important to maintain, with slow heart rates preferred (see ECG).

Diagnostic Studies

Echocardiography is the most valuable technique for assessing mitral stenosis (see Video); (see Video). A scoring system is used to help define which patients are eligible for percutaneous valvuloplasty. One to four points are assigned to each of four observed parameters, with one being the least involvement and four the greatest: mitral leaflet thickening, mitral leaflet mobility, submitral scarring, and commissural calcium. Patients with a total valve score of 8 or less respond best to balloon valvuloplasty. LA size can also be determined by echocardiography: increased size denotes an increased likelihood of atrial fibrillation and thrombus formation. The effective mitral valve area can be determined by planimetering the smallest mitral orifice or by using the continuous-wave Doppler gradient. Some determination of the pulmonary pressure can also be quantitated by measuring the peak RV pressure from the tricuspid velocity jet signal.

Video

Rheumatic mitral stenosis. (Courtesy of B Macrum and E Foster.)

Because echocardiography and careful symptom evaluation provide most of the needed information, cardiac catheterization is used primarily to detect associated valve, coronary, or myocardial disease—usually after the decision to intervene has been made.

Treatment & Prognosis

Mitral stenosis may be present for a lifetime with few or no symptoms, or it may become severe in a few years. In most cases, there is a long asymptomatic phase, followed by subtle limitation of activity. Pregnancy and its associated increase in cardiac output results in an increased transmitral pressure gradient that often precipitates symptoms. Toward the end of pregnancy, the cardiac output is also maintained by an increase in heart rate, further increasing the mitral gradient. Patients with moderate to severe mitral should have the condition corrected prior to becoming pregnant if possible. Patients who become symptomatic can undergo successful surgery, preferably in the third trimester, although balloon valvuloplasty is the treatment of choice if the echo score is low enough.

The onset of atrial fibrillation often precipitates more severe symptoms, which usually improve with control of the ventricular rate or restoration of sinus rhythm. Conversion to and subsequent maintenance of sinus rhythm are most commonly successful when the duration of atrial fibrillation is brief (< 6–12 months) and the LA is not severely dilated (diameter < 4.5 cm). Once atrial fibrillation occurs, the patient should receive warfarin anticoagulation therapy even if sinus rhythm is restored, since atrial fibrillation often recurs even with antiarrhythmic therapy and 20–30% of these patients will have systemic embolization if untreated (see CT scan). Systemic embolization in the presence of only mild to moderate disease is not an indication for surgery but should be treated with warfarin anticoagulation.

Fig.

Computer-based radiograph tomographic scan of the thorax showing thrombus in the left atrium *(black arrow)* of a patient with mitral valve disease. (RA, right atrium; LA, left atrium; Ao, aorta; RV, right ventricle.) (Reproduced, with permission, from Tomoda H et al: Evaluation of left atrial thrombus with computed tomography. Am Heart J 1980;100:306.)

Indications for intervention focus on symptoms such as an episode of pulmonary edema, a decline in exercise capacity, or any evidence for pulmonary hypertension (peak systolic pulmonary pressure > 50 mm Hg). Some experts believe that the presence of atrial fibrillation should be a consideration for an intervention.

Open mitral commissurotomy is now rarely performed and has given way to percutaneous balloon valvuloplasty (see Video). Ten-year follow-up data comparing surgery to balloon valvuloplasty suggest no real difference in outcome between the two modalities. Replacement of the valve is indicated when combined stenosis and regurgitation are present or when the mitral valve echo score is > 8. Percutaneous mitral valvuloplasty has a very low mortality rate (< 0.5%) and low morbidity rate (3–5%). Operative mortality rates are also low: 1–3% in most institutions. Repeat valvuloplasty can be done if the morphology of the valve is suitable. A Maze procedure may be done at the same time to reduce recurrent atrial arrhythmias.

Video
Percutaneous transvenous mitral commissurotomy (PTMC) with Inoue balloon catheter. The balloon inflates distally and then proximally to allow proper positioning across the mitral valve. The mean pressure gradient across the mitral valve is proportionate to the area between the pressure curves and is markedly reduced after PTMC. (Courtesy of T Amidon and T Chou.)

Mechanical mitral prosthetic valves are more prone to thrombosis than aortic valves. Bioprosthetic valves degenerate after about 10–12 years and percutaneous balloon valvuloplasty procedures cannot be done on bioprosthetic valves should stenosis occur. Younger patients and those with end-stage renal disease do least well with bioprosthetic heart valves, although recent data have questioned the role of chronic kidney disease as a major risk factor. Endocarditis prophylaxis is always indicated for prosthetic valves. Percutaneous balloon valvuloplasty can safely be done during pregnancy if symptoms warrant.

When to Refer

- Patients with mitral stenosis should be monitored with yearly examinations and echocardiograms.
- All patients should initially be seen by a cardiologist, who then decides how often the patient needs follow-up with the cardiologist.

Bonow RO et al. 2008 focused update incorporated into the ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. [PMID: 18848134]

Mitral Regurgitation (Mitral Insufficiency)

Essentials of Diagnosis

- Variable causes determine clinical presentation.
- May be asymptomatic for many years (or for life) or may cause left-sided heart failure.
- Pansystolic murmur at the apex, radiating into the axilla; associated with S_3 when regurgitant volume is great.
- ECG shows LA abnormality or atrial fibrillation and LVH; radiograph shows LA and LV enlargement.
- Echocardiographic findings can help decide when to operate.
- For primary mitral regurgitation, surgery is indicated for symptoms or when the LV ejection fraction is < 60% or the echocardiographic LV end-systolic diameter is > 4.0 cm.
- In patients with mitral prolapse and severe mitral regurgitation, early surgery is indicated if mitral repair can be performed.

General Considerations

The components of the mitral valve apparatus include the myocardium below the papillary muscles, the papillary muscles themselves, the chordae, the leaflets, and the mitral annulus. Chordae from both the anterior and posterior leaflets attach to both papillary muscles. When ventricular contraction occurs, the papillary muscles contract first and pull the leaflets toward each other. As the LV pressure rises, the leaflets touch and the rising pressure in the LV pushes the leaflets together (so-called "keystone" effect). The chordae continue to rein in the mitral valve as systole commences and the annulus contracts. All of these components keep the mitral valve from leaking. Failure of any of these components results in mitral regurgitation. Thus, if the papillary muscles are displaced (as in dilated cardiomyopathy), the chordae are too long, the leaflets are too baggy (as in mitral prolapse), or the annulus does not contract (as in annular calcification or cardiomyopathy), then mitral regurgitation will result. Mitral regurgitation places a volume load on the heart (increases preload) but reduces afterload. The result is an enlarged LV with an increased ejection fraction (EF). Over time, the stress of the volume overload weakens the LV; when this occurs, there is a drop in EF and a rise in end-systolic volume.

Clinical Findings

Symptoms and Signs

During LV systole, the mitral leaflets do not close normally, and blood is ejected into the LA as well as through the aortic valve. In acute mitral regurgitation, LA pressure rises abruptly, leading to pulmonary edema if severe. When chronic, the LA enlarges progressively and the increased volume can be handled without a major rise in the LA pressure; the pressure in pulmonary veins and capillaries may rise only transiently during exertion (see illustration). Exertional dyspnea and fatigue progress gradually over many years.

Fig.

Hemodynamically significant mitral incompetence. Structures enlarged: left atrium and left ventricle. (Reproduced, with permission, from Cheitlin MD, Sokolow M, McIlroy MB: *Clinical Cardiology*, 6th ed. Originally published by Appleton & Lange. Copyright © 1993 by The McGraw-Hill Companies, Inc.)

Mitral regurgitation leads to LA enlargement and may cause subsequent atrial fibrillation. Systemic embolization is relatively unusual compared with other conditions causing atrial fibrillation. Mitral regurgitation may predispose to infective endocarditis, although endocarditis prophylaxis is optional.

Clinically, mitral regurgitation is characterized by a pansystolic murmur maximal at the apex, radiating to the axilla and occasionally to the base; a hyperdynamic LV impulse and a brisk carotid upstroke; and a prominent third heart sound due to the increased volume returning to the LV in early diastole ; (Tables 10–2, 10–3).

Diagnostic Studies

Echocardiography is useful in demonstrating the underlying pathologic process (rheumatic, prolapse, flail leaflet, cardiomyopathy), and Doppler techniques provide qualitative and semiquantitative estimates of the severity of mitral regurgitation (see Video). It should be noted that a minor degree of retrograde flow from the closing of the mitral valve occurs almost uniformly and echocardiography/Doppler detects this clinically insignificant regurgitation in many normal individuals. Echocardiographic information concerning LV size and function, LA size, PA pressure, and RV function can be invaluable in planning treatment as well as in recognizing associated lesions. TEE may help reveal the cause of regurgitation and is especially useful in patients who have had mitral valve replacement, in suspected endocarditis, and in identifying candidates for valvular repair. Echocardiographic dimensions and measures of systolic function are critical in deciding the timing of surgery. In the past, exercise radionuclide angiography for measurements of exercise EF or determination of myocardial stress–EF relationships was recommended, but this is now rarely done. There is a growing body of evidence of the usefulness of B-type natriuretic peptide (BNP) in the early identification of LV dysfunction in the presence of mitral regurgitation.

Cardiac MRI is occasionally useful, for example, if specific myocardial causes are being sought (such as amyloid or myocarditis) or if myocardial viability is needed prior to deciding whether to add coronary artery bypass grafting to mitral repair in patients with chronic ischemic mitral regurgitation.

Cardiac catheterization provides a further assessment of regurgitation and its hemodynamic impact along with LV function, resting cardiac output, and PA pressure. Coronary angiography is often indicated to determine the presence of CAD prior to valve surgery in patients with risk factors or those older than age 45 years. In the near future, it may be that cardiac multidetector **CT** may be adequate to screen patients with valvular heart disease for asymptomatic CAD.

Treatment & Prognosis

Mitral Regurgitation

LA enlargement is at times considerable in chronic mitral regurgitation; the degree of LV enlargement usually reflects the severity of regurgitation. Calcification of the mitral valve is less common than in pure mitral stenosis.

Hemodynamically, LV volume overload may ultimately lead to LV failure and reduced cardiac output, but for many years the LV end-diastolic pressure and the cardiac output may be normal at rest. Nonrheumatic mitral regurgitation may develop abruptly, such as with papillary muscle dysfunction following myocardial infarction, valve perforation in infective endocarditis, or ruptured chordae tendineae in mitral valve prolapse.

Acute mitral regurgitation due to endocarditis, myocardial infarction, and ruptured chordae tendineae often requires emergency surgery. Some patients can be stabilized with vasodilators or intra-aortic balloon counterpulsation, which reduce the amount of regurgitant flow by lowering systemic vascular resistance. Patients with chronic lesions may remain asymptomatic for many years. Surgery is necessary when symptoms develop. However, because progressive and irreversible deterioration of LV function may occur prior to the onset of symptoms, early operation is indicated even in asymptomatic patients with a reduced EF (< 60%) or marked LV dilation (end-systolic dimension > 4.0 cm on echocardiography). In some institutions, the calculation of an effective regurgitant orifice area by echocardiogram has proven useful in helping decide the severity of the mitral regurgitation. Regurgitant orifice areas > 40 mm^2 are considered severe. There is controversy regarding the role of afterload reduction in mitral regurgitation, since the lesion inherently results in a reduction in afterload. A heightened sympathetic state has led some to suggest -blockade instead. Most clinicians who monitor patients with chronic mitral regurgitation still prescribe medications, eg, angiotensin-converting enzyme (ACE) inhibitors, to reduce afterload, but there are little supportive data.

Ischemic Heart Disease

When mitral regurgitation is due to papillary dysfunction, it may subside as the infarction heals or LV dilation diminishes. The cause of the regurgitation in most situations is displacement of the papillary muscles and an enlarged mitral annulus rather than true papillary muscle ischemia. In acute infarction, rupture of the papillary muscle may occur with catastrophic results. Transient—but sometimes severe—mitral regurgitation may occur during episodes of myocardial ischemia and contribute to flash pulmonary edema. Patients with dilated cardiomyopathies of any origin may have **secondary mitral regurgitation** due to papillary muscle displacement or dilation of the mitral annulus. In patients with ischemic cardiomyopathy, ventricular reconstructive surgery to restore the mitral apparatus anatomy is under investigation (eg, the Dor procedure). If mitral valve replacement is performed, preservation of the chordae to the native valve helps prevent further ventricular dilation following surgery. Several groups have reported good results with mitral valve repair in patients with LV EFs greater than 30% and secondary mitral insufficiency. Recent guidelines consider it acceptable to attempt mitral valve repair in patients with an EF < 30% or an LV end systolic dimension > 5.5 cm, or both, as long as repair and preservation of the chordate is possible.

When to Refer

All patients with more than mild mitral regurgitation should be referred to a cardiologist for an evaluation. Serial examinations and echocardiograms (usually yearly) should be obtained, and referral made if there is any increase in the LV end-systolic dimensions or a fall in the EF to less than 60%.

Mitral Valve Prolapse

Essentials of Diagnosis

- Single or multiple mid-systolic clicks often heard on auscultation.
- Murmur may be pansystolic or only late in systole.
- Often associated with skeletal changes (straight back, pectus, scoliosis) or hyperreflexivity of joints.
- Echocardiography is confirmatory with prolapse of mitral leaflets in systole into the LA.
- Chest pain and palpitations common symptoms in the young adult.

General Considerations

The significance of **mitral valve prolapse("floppy" or myxomatous mitral valve)** is in dispute because of the frequency with which it is diagnosed in healthy young women (up to 10%); however, this condition can be problematic in the many patients. A hyperadrenergic syndrome has been described, especially in young females, that may be responsible for some of the noncardiac symptoms observed. Fortunately, this syndrome attenuates with age. Some patients have findings of a systemic collagen abnormality (Marfan or Ehlers-Danlos syndrome). In these conditions, a dilated aortic root and aortic regurgitation may coexist with the mitral valve prolapse.

Patients who have only a mid-systolic click usually have no sequelae, but significant mitral regurgitation may develop, occasionally due to rupture of chordae tendineae (flail leaflet). The need for valve repair or replacement increases with age, so that approximately 2% of patients with clinically significant regurgitation over age 60 years will require surgery.

Clinical Findings

Symptoms and Signs

Mitral valve prolapse is usually asymptomatic but may be associated with nonspecific chest pain, dyspnea, fatigue, or palpitations. Most patients are female, many are thin, and some have skeletal deformities such as pectus excavatum or scoliosis. On auscultation, there are characteristic mid-systolic clicks that emanate from the chordae or redundant valve tissue and that may be multiple. If leaflets fail to come together properly, the clicks will be followed by a late systolic murmur. As the mitral regurgitation worsens, the murmur is heard more and more throughout systole. The smaller the LV chamber, the greater the degree of prolapse, and thus auscultatory findings are often accentuated in the standing position.

Diagnostic Studies

The diagnosis is primarily clinical but can be confirmed echocardiographically. Mitral prolapse is often associated with aortic root disease, and any evidence for a dilated aorta by chest radiography should prompt either CT or MRI angiography. If palpitations are an issue, an ambulatory monitor is often helpful to distinguish atrial from ventricular tachyarrhythmias.

Treatment

-Blockers in low doses are used to treat the hyperadrenergic state when present and are usually satisfactory for treatment of arrhythmias. Aspirin has been advocated in the past due to concern regarding systemic emboli, but that practice has been abandoned without evidence for atrial tachyarrhythmias.

Mitral valve repair is favored over valve replacement, and its efficacy has led many to recommend intervention earlier and earlier in the course of the disease process. Mitral repair may include shortening of chordae, chordae transfers, wedge resection of redundant valve tissue, and mitral annular ring to reduce the annular size. Stitching of the leaflets together to create a double orifice mitral valve is also used at times (Alfieri procedure). Mitral repair or replacement can be done through a right minithoracotomy. Robotic devices are also being used to repair these valves. A variety of percutaneous methods for repair of the regurgitant mitral valve are being investigated. These methods include devices to create a double orifice mitral valve by clipping the anterior and posterior leaflets together, devices that are inserted in the coronary sinus to cinch the annulus and make it smaller, and devices that can be inserted onto the annulus from the ventricular side that can pull the annulus inward and reduce annular circumference. Only the mitral clip device has passed phase 2 trials with encouraging results to date. Endocarditis prophylaxis for most situations is no longer recommended.

When to Refer

- All patients with mitral valve prolapse and audible mitral regurgitation should be seen at least once and then periodically by a cardiologist. Those with only mitral clicks need not.

- Periodic echocardiography is warranted to assess LV size (especially end-systolic dimensions) and EF.

Aortic Stenosis

Essentials of Diagnosis

- Congenital bicuspid aortic valve, usually asymptomatic until middle or old age.
- "Degenerative" or calcific aortic stenosis; same risk factors as atherosclerosis.
- Symptoms likely once the peak echo gradient is > 64 mm Hg.
- Delayed and diminished carotid pulses.
- Soft, absent, or paradoxically split S_2.
- Harsh systolic murmur, sometimes with thrill along left sternal border, often radiating to the neck; may be louder at apex in older patients.
- ECG usually shows LVH; calcified valve on radiography or fluoroscopy.
- Echocardiography/Doppler is diagnostic.
- Surgery indicated for symptoms. Surgical risk is typically low even in the very elderly.

- Surgery considered for asymptomatic patients with severe aortic stenosis.

General Considerations

There are two common clinical scenarios in which aortic stenosis is prevalent (see illustration). The first is due to a congenitally abnormal **unicuspid** or **bicuspid valve,** rather than tricuspid. Symptoms at times occur in young or adolescent individuals if severe, but more often emerge at age 50–65 years when calcification and degeneration of the valve becomes manifest. A dilated ascending aorta, primarily due to an intrinsic defect in the aortic media, may accompany the bicuspid valve. Coarctation of the aorta is also seen in a number of patients with congenital aortic stenosis. A second group develops what has traditionally been called **degenerative or calcific aortic stenosis,** which is thought to be related to calcium deposition due to processes similar to what occurs in atherosclerotic vascular disease. Approximately 25% of patients over age 65 years and 35% of those over age 70 years have echocardiographic evidence of aortic sclerosis. About 10–20% of these will progress to hemodynamically significant aortic stenosis over a period of 10–15 years. Certain genetic markers are now being discovered that are associated with aortic stenosis (most notably Notch 1), so a genetic component appears likely, at least in some patients.

Fig.

Aortic stenosis. Structures enlarged: left ventricle (thickened); poststenotic dilation of the aorta. (Reproduced, with permission, from Cheitlin MD, Sokolow M, McIlroy MB: *Clinical Cardiology*, 6th ed. Originally published by Appleton & Lange. Copyright © 1993 by The McGraw-Hill Companies, Inc.)

Thus, aortic stenosis has become the most common surgical valve lesion in developed countries, and many patients are elderly. The risk factors include hypertension, hypercholesterolemia, and smoking. Hypertrophic obstructive cardiomyopathy may also coexist with valvular aortic stenosis.

Clinical Findings

Symptoms and Signs

Aortic stenosis produces a progressive afterload increase on the LV. To reduce wall stress, the ventricle hypertrophies by laying sarcomeres on top of each other, and increasing the wall thickness. At times, severe LVH ensues. Eventually, the hypertrophy may lead to myocardial dysfunction. Since the EF measurement is afterload dependent, it is frequently difficult to sort out whether the low EF is due to increased afterload or to myocardial dysfunction.

Slightly narrowed, thickened, or roughened valves (aortic sclerosis) or aortic dilation may produce the typical ejection murmur of aortic stenosis. In mild or moderate cases where the valve is still pliable, an ejection click may precede the murmur. The characteristic systolic ejection murmur is heard at the aortic area and is usually transmitted to the neck and apex. In some cases, only the high-pitched components of the murmur are heard at the apex, and the murmur may sound like mitral regurgitation (so-called Gallaverdin phenomenon). In severe aortic stenosis, a palpable LV heave or thrill, a weak to absent aortic second sound, or reversed splitting of the second sound is present (see Table 10–2; ;). When the valve area is less than 0.8–1 cm^2 (normal, 3–4 cm^2), ventricular systole becomes prolonged and the typical carotid pulse pattern of delayed upstroke and low amplitude is present. This may be an unreliable finding, however, in older patients with extensive arteriosclerotic vascular disease. LVH increases progressively, with resulting elevation in ventricular end-diastolic pressure (see x-ray). Cardiac output is maintained until the stenosis is severe (with a valve area < 0.8 cm^2). LV failure, angina pectoris, or syncope may be presenting symptoms and signs of aortic stenosis; importantly, all occur with exertion.

Symptoms of failure may be sudden in onset or may progress gradually. Angina pectoris frequently occurs in aortic stenosis due to underperfusion of the endocardium. Of patients with calcific aortic stenosis and angina, 50% have significant associated CAD. Syncope is typically exertional and a late finding. Syncope occurs with exertion as the LV pressures rises, stimulating the LV baroreceptors to cause peripheral vasodilation. This vasodilation results in the need for an increase in stroke volume, which increases the LV systolic pressure again, creating a cycle of vasodilation and stimulation of the baroreceptors that eventually results in a drop in BP, as the stenotic valve prevents further increase in stroke volume. Less commonly, syncope may be due to arrhythmias (usually ventricular tachycardia but sometimes AV block as calcific invasion of the conduction system from the aortic valve may occur).

Diagnostic Studies

The clinical assessment of the severity of aortic stenosis may be difficult, especially when there is reduced cardiac output or significant associated aortic regurgitation. The ECG reveals LVH or suggestive repolarization changes in most patients, but can be normal in up to 10% (see ECG). The chest radiograph may show a normal or enlarged cardiac silhouette, calcification of the aortic valve, and dilation and calcification of the ascending aorta (see x-ray); (see x-ray). The echocardiogram provides useful data about aortic valve calcification and opening and LV thickness and function, while Doppler can provide an excellent estimate of the aortic valve gradient. The peak Doppler gradient is derived by squaring the maximal flow velocity through the valve orifice and multiplying times 4; thus, a 4 m/s maximum velocity gradient translates into a 64 mm Hg peak Doppler gradient. Valve area estimation by echocardiography is less reliable. Cardiac catheterization mostly provides an assessment of the hemodynamic consequence of the aortic stenosis, and a look at the coronary arteries. In younger patients, and in patients with high aortic gradients the aortic valve need not be crossed at catheterization. If it is crossed, the valve gradient can be measured at catheterization and an estimated valve area calculated; a valve area below 1.0 cm^2 indicates significant stenosis in the newest ACC/AHA guidelines. Aortic regurgitation can be semiquantified by aortic root angiography. In patients with a low EF and both low output and a low valve gradient, it may be unclear if an increased afterload is responsible for the low EF or if there is an associated cardiomyopathy. To sort this out, the patient should be studied at baseline and then during an intervention that increases cardiac output (eg, dobutamine or nitroprusside infusion). If the valve area increases, the flow-limiting problem is not the valve, but rather the cardiomyopathy, and surgery is not warranted. If the valve area remains unchanged at the higher outputs, then the valve is considered flow limiting and surgery is indicated. Recent data have suggested the use of BNP may provide prognostic data in the setting of poor LV function and aortic stenosis. A BNP > 550 pg/mL has been associated with a poor outcome in these patients regardless of the results of dobutamine testing.

Prognosis & Treatment

Following the onset of heart failure, angina, or syncope, the prognosis without surgery is poor (50% 3-year mortality rate). Medical treatment may stabilize patients in heart failure, but surgery is indicated for all symptomatic patients with evidence of significant aortic stenosis. Valve replacement is usually not indicated in asymptomatic individuals, though a class II indication is to operate once the peak valve gradient by Doppler exceeds 64 mm Hg or the mean exceeds 40 mm Hg. Stress testing and perhaps the use of BNP may help identify patients who deny symptoms but are actually compromised from a ventricular function standpoint.

The surgical mortality rate for valve replacement is low, even in the elderly, and ranges from 2% to 5%. This low risk is due to the dramatic hemodynamic improvement that occurs with relief of the increased afterload. Mortality rates are substantially higher when there is an associated ischemic cardiomyopathy. Severe coronary lesions are usually bypassed at the same time. Around one-third to one-half of all patients with aortic stenosis have CAD.

The interventional options in patients with aortic stenosis are variable and dependent on the patient's lifestyle and age. In the young and adolescent patient, percutaneous valvuloplasty still has a role. Balloon valvuloplasty is less effective and is associated with early restenosis in the elderly, and thus is rarely used. Data suggest aortic balloon valvuloplasty has an advantage only in those with preserved LV function, and such patients are usually excellent candidates for surgical aortic valve replacement (AVR) (see Video). The Ross procedure is generally still considered a viable option in younger patients, and it is performed by moving the patient's own pulmonary valve to the aortic position and replacing the pulmonary valve with a homograft (or rarely a bioprosthetic valve). However, dilation of the pulmonary valve autograft and consequent aortic regurgitation, plus early stenosis of the pulmonary homograft in the pulmonary position, has reduced the enthusiasm for this approach in many institutions. Middle-aged adults generally can take the anticoagulation therapy necessary for the use of mechanical AVR, so most undergo AVR with a bileaflet mechanical valve. If the aortic root is severely dilated as well (> 5.0 cm), then the valve may be housed in a Dacron sheath (Bentall procedure) and the root replaced as well. Alternatively, a human homograft root and valve replacement may be used. In the elderly, bioprosthetic (either porcine or bovine pericardial) valves with a life expectancy of about 10–15 years are routinely used to avoid need for anticoagulation. Recent data favor the bovine pericardial valve over the porcine pericardial valve. If the aortic annulus is small, a bioprosthetic valve with a short sheath can be sewn to the aortic wall (the stentless AVR) rather than sewing the prosthetic annulus to the aortic annulus.

Video
Percutaneous balloon valvuloplasty of calcific aortic stenosis. Hemodynamic tracings of simultaneously recorded aortic and left ventricular pressure waveforms are depicted. The mean pressure gradient across the aortic valve is proportionate to the area between the pressure

curves and is markedly reduced after valvuloplasty. (Courtesy of T Amidon and T Chou.)

Anticoagulation is required with the use of mechanical valves, and the international normalized ratio (INR) should be maintained between 2.0 and 2.5. Mechanical aortic valves are less subject to thrombosis than mechanical mitral valves.

There is growing interest in developing a percutaneous approach to AVR. Both a retrograde approach (from the aorta) and an antegrade approach (from the ventricles by way of a transseptal catheter across the atrial septum) are being investigated. The devices being tested use either a stent with a trileaflet bovine pericardial valve constructed in it, or a stent with a large valve from a cow's jugular vein mounted inside. Preliminary data are encouraging.

When to Refer

- All patients with an aortic murmur and echocardiographic evidence for aortic stenosis (estimated peak valve gradient > 30 mm Hg) should be referred to a cardiologist for evaluation and to determine the frequency of follow-up.
- Any patients with symptoms suggestive of aortic stenosis should be seen by a cardiologist.

Aortic Regurgitation (Chronic Regurgitation)

Essentials of Diagnosis

- Usually asymptomatic until middle age; presents with left-sided failure or chest pain.
- Wide pulse pressure.
- Hyperactive, enlarged LV.
- Diastolic murmur along left sternal border.
- ECG shows LVH; radiograph shows LV dilation.
- Echocardiography/Doppler is diagnostic.
- Afterload reduction may be beneficial if the LV is dilated (LV end-diastolic dimension > 5.0 cm) or there is evidence for systolic blood pressure elevation.
- Surgery indicated for symptoms, EF < 55%, or LV

end-systolic dimension > 5.0 cm.

General Considerations

Rheumatic aortic regurgitation has become much less common than in the preantibiotic era, and nonrheumatic causes now predominate. These include congenitally bicuspid valves, infective endocarditis, and hypertension. Many patients have aortic regurgitation secondary to aortic root diseases such as cystic medial necrosis, Marfan syndrome, or aortic dissection. Rarely, inflammatory diseases, such as ankylosing spondylitis or Reiter syndrome, may be causative.

Chronic aortic regurgitation presents both an increased preload and an increased afterload to the LV. The response to these effects is to hypertrophy by laying sarcomeres end to end, increasing the LV chamber size greater than the wall thickness (eccentric hypertrophy). The amount of LVH in chronic aortic regurgitation is substantial and greater than that seen in aortic stenosis or mitral regurgitation.

Clinical Findings

Symptoms and Signs

The clinical presentation is determined by the rapidity with which regurgitation develops. In chronic regurgitation, the only sign for many years may be a soft aortic diastolic murmur . As the severity of the aortic regurgitation increases, diastolic BP falls, and the LV progressively enlarges. Most patients remain asymptomatic even at this point. LV failure is a late event and may be sudden in onset. Exertional dyspnea and fatigue are the most frequent symptoms, but paroxysmal nocturnal dyspnea and pulmonary edema may also occur. Angina pectoris or atypical chest pain may occasionally be present. Associated CAD and presyncope or syncope are less common than in aortic stenosis.

Audio
Severe aortic regurgitation due to aortic valve endocarditis. Note the rough 3/6 mid-systolic murmur, then S2, a musical early diastolic murmur, and a mid-diastolic Austin-Flint murmur. (Reproduced, with permission, from T. Anthony Don Michael, MD: *Mastering Auscultation* [CD-ROM], McGraw-Hill, 2000.)

Hemodynamically, because of compensatory LV dilation, patients eject a large stroke volume, which is adequate to maintain forward cardiac output until late in the course of the disease. LV diastolic pressure may rise when heart failure occurs. Abnormal LV systolic function, as manifested by reduced EF (< 55%) and increasing end-systolic LV volume (> 5 cm), is a sign that surgical intervention is warranted.

The major physical findings in **chronic aortic regurgitation** relate to the high stroke volume being ejected into the systemic vascular system with rapid runoff as the regurgitation takes place (see Table 10–2). This results in a wide arterial pulse pressure. The pulse has a rapid rise and fall (water-hammer pulse or Corrigan pulse), with an elevated systolic and low diastolic pressure. The large stroke volume is also responsible for characteristic findings such as Quincke pulses (nailbed capillary pulsations), Duroziez sign (to and fro murmur over a partially compressed peripheral artery, commonly the femoral), and Musset sign (head bob with each pulse). In younger patients, the increased stroke volume may summate with the reflected wave from the periphery and create an even higher systolic pressure in the extremity compared with the central aorta. Since the peripheral bed is much larger in the leg than the arm, the BP in the leg may be over 40 mm Hg higher than in the arm (Hill sign). The apical impulse is prominent, laterally displaced, usually hyperdynamic, and may be sustained. A systolic murmur is usually present and may be quite soft and localized; the aortic diastolic murmur is usually high-pitched and decrescendo . A mid or late diastolic low-pitched mitral murmur (Austin Flint murmur) may be heard in advanced aortic regurgitation, owing to partial obstruction of mitral inflow produced by partial closure of the mitral valve by the regurgitant jet and the rapidly rising LV diastolic pressure.

In **acute aortic regurgitation** (usually from aortic dissection or infective endocarditis), LV failure is manifested primarily as pulmonary edema and may develop rapidly; surgery is urgently required in such cases. Patients with acute aortic regurgitation do not have the dilated LV of chronic aortic regurgitation and the extra volume is handled poorly. For the same reason, the diastolic murmur is shorter and may be minimal in intensity, and the pulse pressure may not be widened, making clinical diagnosis difficult. The mitral valve may close prematurely even before systole has been initiated (pre-closure) due to the rapid rise in the LV diastolic pressure, and the first heart sound is thus diminished or inaudible.

Diagnostic Studies

The ECG usually shows moderate to severe LVH. Radiographs show cardiomegaly with LV prominence and sometimes a dilated aorta.

Echocardiography demonstrates the major diagnostic features, including whether the lesion involves the proximal aortic root and what valvular disease is present. Serial assessments of LV size and function are critical in determining the timing for valve replacement. Color Doppler techniques can qualitatively estimate the severity of regurgitation, though some "mild" regurgitation due to aortic valve closure is not uncommon and should not be overinterpreted. Cardiac MRI and CT can estimate aortic root size, particularly when there is concern for an ascending aneurysm. MRI can provide a regurgitant fraction to help confirm severity. Scintigraphic studies are infrequently used but can quantify LV function and functional reserve during exercise. Exercise increases the heart rate and reduces the diastolic time, resulting in less aortic regurgitation per beat; this complicates interpretation of the exercise EF. Cardiac catheterization may be unnecessary in younger patients, particularly those with acute aortic regurgitation, but can help define hemodynamics, aortic root abnormalities, and associated CAD preoperatively in older patients.

Treatment & Prognosis

Aortic regurgitation that appears or worsens during or after an episode of infective endocarditis or aortic dissection may lead to acute severe LV failure or subacute progression over weeks or months. The former usually presents as pulmonary edema; surgical replacement of the valve is indicated even during active infection. These patients may be transiently improved or stabilized by vasodilators.

Chronic regurgitation has a long natural history, but the prognosis without surgery becomes poor when symptoms occur. Since aortic regurgitation places both a volume and afterload increase on the LV, medications that decrease afterload can reduce regurgitation severity. Current recommendations continue to advocate afterload reduction in aortic regurgitation, though the data are derived from very few patients, and its use remains controversial. Most clinicians prescribe ACE inhibitors whenever the LV diastolic size is increased > 5.0 cm on echocardiogram or if there is evidence for systemic hypertension. There are experimental data that suggest ACE-inhibitors may actually be harmful, however. -Blocker therapy may slow the rate of aortic dilation in Marfan syndrome by reducing the dP/dt, though the slower heart rates that result may theoretically increase the diastolic time and the amount of regurgitation per beat, and increase the volume overload on the heart. Patients with aortic regurgitation need to be monitored serially by echocardiography. Surgery is indicated once symptoms emerge or for any evidence of LV dysfunction. LV dysfunction in this situation can be defined by echocardiography if the EF is < 55% or if the LV end-systolic dimension is > 5.0 cm, even in the asymptomatic patient. In addition, aortic root diameters of > 4.5 cm in Marfan or > 5.0 cm in non-Marfan patients are indications for surgery to avoid rapid expansion. Although the operative mortality rate is higher when LV function is severely impaired, valve replacement or repair is still indicated, since LV function often improves and the long-term prognosis is thereby enhanced even in this situation. The issues with AVR covered in the above section concerning aortic stenosis pertain here. Currently, however, there are no percutaneous approaches to aortic regurgitation. The choice of prosthetic valve for AVR depends on the patient's age and compatibility with warfarin anticoagulation.

The operative mortality rate is usually in the 3–5% range. Aortic regurgitation due to aortic root disease requires repair or replacement of the root. Though valve-sparing operations have improved recently, most patients with root replacement undergo valve replacement at the same time. Root replacement procedures include the Ross procedure (moving the pulmonary valve to the aortic position and replacing the pulmonary valve with a homograft or, less commonly, bioprosthetic valve), the direct homograft for the aortic root and valve, and the Bentall procedure (the use of a Dacron sheath with a mechanical or bioprosthetic valve sewn in place). Root replacement in association with valve replacement requires reanastomosis of the coronary arteries, and thus the procedure is more complex than valve replacement alone. Following surgery, LV size usually decreases and LV function generally improves even when the baseline

EF is depressed.

When to Refer

- Patients with audible aortic regurgitation should been seen, at least initially, by a cardiologist and decision made as to how often the patient needs follow-up.
- Patients with a dilated aortic root should be monitored by a cardiologist, since other imaging studies may be required to decide surgical timing.

Tricuspid Stenosis

Essentials of Diagnosis

- Female predominance.
- History of rheumatic heart disease. Carcinoid disease more common etiology in the United States.
- Elevated JVP with prominent *a* wave.
- Right heart failure after tricuspid surgery or in rheumatic disease or carcinoid syndrome.
- Echocardiography/Doppler is key to diagnosis.
- Mean valve gradient > 5 mm Hg by

echocardiography indicates severe tricuspid stenosis.

General Considerations

Tricuspid stenosis is usually rheumatic in origin, though in the United States, tricuspid stenosis is more commonly due to tricuspid valve repair or replacement or to the carcinoid syndrome than to rheumatic fever. Tricuspid regurgitation frequently accompanies the lesion. It should be suspected when "right heart failure" appears in the course of mitral valve disease or in the postoperative period after tricuspid valve repair or replacement.

Clinical Findings

Symptoms and Signs

Tricuspid stenosis is characterized by right heart failure and hepatomegaly, ascites, and dependent edema. A giant *a* wave is seen in the JVP, which is elevated (Table 10–2). The typical diastolic rumble along the lower left sternal border mimics mitral stenosis, though the rumble increases with inspiration. In sinus rhythm, a presystolic liver pulsation may be found.

Diagnostic Studies

In the absence of atrial fibrillation, the ECG reveals RA enlargement. The chest radiograph may show marked cardiomegaly with a normal PA size. A dilated SVC and azygous vein may be evident.

The normal valve area of the tricuspid valve is 10 cm^2, so significant stenosis must be present to produce a gradient. Hemodynamically, a mean diastolic pressure gradient of > 5 mm Hg is considered significant, though even a 2 mm Hg gradient can be considered abnormal. This can be demonstrated by echocardiography or at cardiac catheterization.

Treatment & Prognosis

Tricuspid stenosis may be progressive, eventually causing severe right heart failure. Initial therapy is directed at reducing the fluid congestion, with diuretics the mainstay. When there is considerable bowel edema, torsemide may have an advantage over other loop diuretics, such as furosemide, because it is better absorbed from the gut. Aldosterone inhibitors may also help if there is liver engorgement or ascites. Neither surgical nor percutaneous valvuloplasty is effective for tricuspid stenosis, as residual tricuspid regurgitation is common. Tricuspid valve replacement is clearly the preferred surgical approach. Mechanical tricuspid valve replacement is rarely done because the low flow predisposes to thrombosis and because the mechanical valve cannot be crossed should the need arise for right heart catheterization or pacemaker implantation. Therefore, bioprosthetic valves are almost always used. Often tricuspid valve replacement is done in conjunction with mitral valve replacement for mitral stenosis.

Tricuspid Regurgitation

Essentials of Diagnosis

- Frequently occurs in patients with pulmonary or cardiac disease, especially if pulmonary hypertension is present.
- Systolic *c*-*v* wave in jugular venous pulsations.
- Holosystolic murmur along left sternal border, which increases with inspiration.
- Echocardiography useful in determining cause (low- or high-pressure tricuspid regurgitation).

General Considerations

The tricuspid valve apparatus differs in many ways from the mitral valve apparatus. Besides having three leaflets rather than two, the tricuspid valve has many chordae that attach to the RV endocardium rather than to discrete papillary muscles, and chordal attachments to the RV septum. Tricuspid valvular incompetence often occurs whenever there is RV dilation from any cause. As tricuspid regurgitation increases, the RV size increases further, and this in turn worsens the tricuspid regurgitation. The causes of tricuspid regurgitation thus relate to anatomic issues with either the valve itself or to the RV geometry. An enlarged, dilated RV may be present if there is pulmonary hypertension for any reason, in severe pulmonic regurgitation, or in cardiomyopathy. The RV may be injured from myocardial infarction or may be inherently dilated due to infiltrative diseases (RV dysplasia or sarcoidosis). The RV dilation is often secondary to left heart failure. Inherent abnormalities of the tricuspid valve include Ebstein anomaly (displacement of the septal and posterior, but never the anterior, leaflets into the RV) (see x-ray), tricuspid valve prolapse, carcinoid plaque formation, collagen disease inflammation, tricuspid endocarditis, or RV pacemaker catheter injury.

Clinical Findings

Symptoms and Signs

The symptoms and signs of tricuspid regurgitation are identical to those resulting from RV failure due to any cause. As a generality, the diagnosis can be made by careful inspection of the JVP (Table 10–2). The JVP waveform should decline during ventricular systole (the x descent). The timing of this decline can be observed by palpating the opposite carotid artery. As tricuspid regurgitation worsens, more and more of this valley in the JVP is filled with the regurgitant wave until all of the x descent is obliterated and a positive systolic waveform will be noted in the JVP. An associated tricuspid regurgitation murmur may or may not be present and can be distinguished from mitral regurgitation by the left parasternal location and increase with inspiration . An S_3 may accompany the murmur and is related to the high flow returning from the RA. Cyanosis may be present if the increased RA pressure stretches the atrial septum and opens a PFO or there is a true ASD (eg, in about 50% of patients with Ebstein anomaly).

Diagnostic Studies

The ECG is usually nonspecific, though atrial fibrillation is not uncommon. The chest radiograph may reveal evidence for an enlarged RA or dilated azygous vein and pleural effusion. The echocardiogram helps assess severity of tricuspid regurgitation, PA pressure, and RV size and function. A paradoxically moving interventricular septum may be present. Catheterization confirms the presence of the regurgitant wave in the RA and elevated RA pressures. If the PA or RV systolic pressure is < 40 mm Hg, primary tricuspid regurgitation should be suspected.

Treatment & Prognosis

Minor tricuspid regurgitation is well tolerated. Severe tricuspid regurgitation results in hepatomegaly, edema, and ascites. In patients in the intensive care unit, tricuspid regurgitation may result in erroneous thermodilution cardiac output measurements because the recirculation of the saline bolus back to the RA reduces the temperature signal to noise required to perform the measurement. When present, bowel edema may reduce the effectiveness of oral furosemide, and intravenous diuretics should initially be used. Torsemide is better absorbed in this situation. Aldosterone antagonists have a role as well, particularly if ascites is present. At times, the efficacy of loop diuretics can be enhanced by adding a thiazide diuretic.

Definitive treatment usually requires elimination of the cause of the tricuspid regurgitation. If the problem is left heart disease, then treatment of the left heart issues may lower pulmonary pressures, reduce RV size, and resolve the tricuspid regurgitation. Treatment for primary and secondary causes of pulmonary hypertension will generally reduce the tricuspid regurgitation. If surgery is contemplated for other reasons, especially mitral valve disease, then tricuspid annuloplasty is generally performed at the same time with a valvular ring sewn in place. Annuloplasty without insertion of a prosthetic ring (DeVega annuloplasty) may also be effective to reduce the annular dilation. The valve leaflet itself can occasionally be repaired in tricuspid valve endocarditis. In years past, in patients with tricuspid regurgitation due to endocarditis from substance abuse, the tricuspid valve has been temporarily removed to aid in cure of the endocarditis, though it must eventually be replaced (usually by 3–6 months); this practice is less common now. If there is an inherent defect in the tricuspid apparatus that cannot be repaired, then replacement of the tricuspid valve is warranted. Almost always, a bioprosthetic valve, and not a mechanical valve, is used. Anticoagulation is not required for bioprosthetic valves unless there is associated atrial fibrillation.

Pulmonic Regurgitation

Essentials of Diagnosis

- Most cases are due to pulmonary hypertension.
- Loud diastolic (Graham Steell) murmur in high-pressure pulmonic regurgitation.
- Soft or no murmur in low-pressure pulmonic regurgitation.
- Echocardiogram is definitive in high-pressure but

may be less helpful in low-pressure pulmonic regurgitation.

- Low-pressure pulmonic regurgitation is well tolerated.

General Considerations

Pulmonary valve regurgitation can be divided into **high-pressure causes** (due to pulmonary hypertension) and **low-pressure causes** (usually due to a dilated pulmonary annulus [idiopathic or traumatic] or to plaque from carcinoid disease or following surgical repair). It may be iatrogenic, eg, frequently occurring after repair of tetralogy of Fallot. Because the RV tolerates a volume load better than a pressure load, it tends to tolerate pulmonic regurgitation well.

Clinical Findings

On examination, a hyperdynamic RV can usually be palpated. If the PA is enlarged, it may be palpated along the left sternal border. P_2 will be palpable in pulmonary hypertension and both systolic and diastolic thrills are occasionally noted. On auscultation, the second heart sound may be widely split due to prolonged RV systole. Systolic clicks may be noted as well as a right-sided gallop. In high-pressure pulmonic regurgitation, the pulmonary diastolic (Graham Steell) murmur is readily audible . It is often due to a dilated pulmonary annulus.

The murmur increases with inspiration and diminishes with the Valsalva maneuver. In low-pressure pulmonic regurgitation, the PA diastolic pressure may be only a few mm Hg higher than the RV diastolic pressure, and there is little diastolic gradient to produce a murmur or characteristic echocardiography/Doppler findings. At times, only contrast angiography or MRI of the main PA will show the free flowing pulmonic regurgitation in this situation.

The ECG is generally of little value. The chest radiograph may show only the enlarged RV and PA. Echocardiography may demonstrate evidence of RV volume overload (paradoxic septal motion), and Doppler can determine peak systolic RV pressure and reveal any associated tricuspid regurgitation. The size of the main PA can be determined and color flow Doppler can demonstrate the pulmonic regurgitation, particularly in the high-pressure situation. Cardiac MRI and CT can be useful for assessing the size of the PA, for imaging the jet lesion, for excluding other causes of pulmonary hypertension (eg, thromboembolic disease, peripheral PA stenosis), and for evaluating RV function. MRI provides a regurgitant fraction to help quantitate the degree of pulmonic regurgitation.

Treatment & Prognosis

Pulmonic regurgitation rarely needs specific therapy other than treatment of the primary cause. In low-pressure pulmonic regurgitation due to surgical patch repair of tetralogy of Fallot, pulmonary valve replacement may be indicated if RV enlargement or dysfunction is present. In tetralogy of Fallot, the QRS will widen as RV function declines and the ECG is helpful here. In carcinoid heart disease, pulmonary valve replacement with a porcine bioprosthesis may be undertaken, though the plaque from this disorder eventually covers the prosthetic valve and this tends to limit the lifespan of these valves. In high-pressure pulmonic regurgitation, treatment to control the cause of the pulmonary hypertension is key.

Gaynor JW. Severe pulmonary insufficiency should be conservatively treated. Cardiol Young. 2005 Feb;15 Suppl 1:68–71. [PMID: 15934695]

Choice & Management of Prosthetic Valves

Less invasive surgical procedures for valve replacement have improved over the past few decades. There are now mini-incisional approaches to aortic, mitral, and tricuspid valve replacement and repair ; . Percutaneous valvuloplasty has replaced surgical commissurotomy for mitral stenosis in most cases. However, percutaneous aortic valvuloplasty is moderately effective only in children and adolescents; it has a very limited role in adults. Neither surgical nor percutaneous tricuspid valvuloplasty is very effective.

Audio

Prosthetic mitral valve sounds. Note the loud closing click of the mitral valve, a second sound and a softer closing click. This sound is heard at the apex of the heart in the mitral area and signifies the presence of non-biological prosthetic mitral valve.” (Reproduced, with permission, from T. Anthony Don Michael, MD: *Mastering Auscultation* [CD-ROM], 2000.)

Audio

Prosthetic aortic valve. Note the crisp click of a prosthetic non-biological valve. A2 is the loudest portion of the second heart sound (S2), consistent with a prosthetic aortic valve.” (Reproduced, with permission, from T. Anthony Don Michael, MD: *Mastering Auscultation* [CD-ROM], 2000.)

Repair of the mitral valve is successful in appropriate patients and has lowered the threshold for intervention in mitral regurgitation. Some experts recommend that all mitral prolapse patients with mitral regurgitation undergo mitral valve repair even when other indications are not present. However, to recommend this option, the surgeon performing the procedure must have extensive experience with excellent results. When tricuspid regurgitation is present and mitral valve repair or replacement is planned, tricuspid repair is now a class I recommendation. Aortic valve sparing procedures are also improving and may obviate the need for AVR, especially in patients undergoing root replacement. Early experience, though, with aortic valve repair is mixed. Direct valvular repair and removal of vegetations are also viable options in some patients with endocarditis.

The choice of prosthetic valve depends on a variety of considerations, such as assessing the expected survival of the patient versus the durability of the valve and the safety of warfarin for the patient. Bioprosthetic valves usually have a life expectancy of 10–15 years, but less in young patients, those on dialysis, or those with hypercalcemia. The lifespan of bovine pericardial valves is somewhat longer than porcine valves, and these are becoming the favorite bioprostheses. Bioprosthetic valves, homografts, and the Ross procedure (replacement of the aortic valve with the patient's own pulmonary valve, then replacement of the removed pulmonary valve with a homograft) do not require anticoagulation with warfarin, though current guidelines suggest warfarin be used for 3 months after valve implantation to allow for endothelial growth over the sewing ring. This latter recommendation is controversial. Mechanical valves have a much longer lifespan, but all require use of warfarin (and frequently aspirin as an adjunct). The long-term risk of warfarin depends on patient compliance and whether there is coexisting disease that may predispose to bleeding.

Mechanical mitral valve prostheses pose a greater risk for thrombosis than mechanical aortic valves. For that reason, the INR should be kept between 2.5 and 3.5 for mechanical mitral prosthetic valves but can be kept between 2.0 and 2.5 for mechanical aortic prosthetic valves. Enteric-coated aspirin (81 mg once daily) is given to patients with both types of mechanical valves but appears to be more important for mitral valve prostheses and for both types of valves when other risk factors are present, such as atrial fibrillation, a reduced EF, a hypercoagulable state, associated CAD, peripheral vascular disease, or a history of CVA.

Warfarin causes fetal skeletal abnormalities in about 2% of women who become pregnant while taking warfarin, so every effort is made to defer valve replacement in women until after childbearing age. However, if a woman with a mechanical valve becomes pregnant while taking warfarin, the risk of stopping warfarin is higher for the mother than the risk of continuing warfarin for the fetus. The risk of warfarin to the fetal skeleton is greatest during the first trimester, so if pregnancy is planned in a woman with a mechanical valve, unfractionated heparin is often used temporarily during the first trimester. After the first trimester, warfarin use is safe again until 2 weeks before planned delivery, when the patient should be switched back to unfractionated heparin. Low-molecular-weight heparin has not been shown to be effective and should not be substituted for unfractionated heparin in the pregnant patient with a mechanical heart valve.

When patients with mechanical valves must undergo noncardiac surgery, the risk of thrombosis from stopping warfarin versus the risk of excessive bleeding from continuing warfarin must be weighed. In general, for bileaflet aortic mechanical valves, warfarin can be stopped 5 days ahead of the surgical procedure and resumed the night of the procedure with no preprocedural "bridging". After the procedure, unfractionated heparin or low-molecular-weight heparin can be used until the INR is 2.0. In patients with a bileaflet mitral valve, warfarin may be stopped 5 days ahead of time and bridging with either unfractionated heparin or low-molecular-weight heparin is often used preoperatively if the INR falls below 2.0. The last dose of low-molecular-weight heparin should be half the therapeutic dose and be given 24 hours before any procedure. If unfractionated heparin is used, it should be stopped 4 hours before the procedure. As with AVR, warfarin is generally started within 24 hours after surgery, but heparin should not be started for 48–72 hours or until hemostasis is secured. Heparin therapy should be continued until the INR is > 2.0.

Coronary Heart Disease: Introduction

Coronary heart disease, or atherosclerotic CAD, is the number one killer in the United States and worldwide. Every minute, an American dies of coronary heart disease. About 38% of people who experience an acute coronary event, either angina or myocardial infarction, will die of it in the same year. Death rates of coronary heart disease have declined every year since 1968, with about half of the decline from 1980 to 2000 due to treatments and half due to improved risk factors. Coronary heart disease is still responsible for approximately one of five deaths and over 600,000 deaths per year in the United States. Coronary heart disease afflicts nearly 16 million Americans and the prevalence rises steadily with age; thus, the aging of the US population promises to increase the overall burden of coronary heart disease.

Risk Factors for CAD

Most patients with coronary heart disease have some identifiable risk factor. These include a positive family history (the younger the onset in a first-degree relative, the greater the risk), male gender, blood lipid abnormalities, diabetes mellitus, hypertension, physical inactivity, abdominal obesity, and cigarette smoking, psychosocial factors, consumption of too few fruits and vegetables and too much alcohol. Smoking remains the number one preventable cause of cardiovascular disease worldwide. Although smoking rates have declined in the United States in recent decades, 19% of women and 23% of men smoke. According to the World Health Organization, 1 year after quitting, the risk of coronary heart disease decreases by 50%. Various interventions have been shown to increase the likelihood of successful smoking cessation (see Chapter 1: Disease Prevention &

Health Promotion).

Hypercholesterolemia and other lipid abnormalities provide an important modifiable risk factor for coronary heart disease. Risk increases progressively with higher levels of low-density lipoprotein (LDL) cholesterol and declines with higher levels of high-density lipoprotein (HDL) cholesterol. Composite risk scores, such as the Framingham score (see Table 28–2), provide estimates of 10-year probability of development of coronary heart disease that can guide primary prevention strategies.

The metabolic syndrome is defined as a constellation of three or more of the following: abdominal obesity, triglycerides 150 mg/dL, HDL cholesterol < 40 mg/dL for men and < 50 mg/dL for women, fasting glucose 110 mg/dL, and hypertension. This syndrome is increasing in prevalence at an alarming rate. Related to the metabolic syndrome, the epidemic of obesity in the United States is likewise a major factor contributing to coronary heart disease risk. Data from National Health and Nutrition Examination Survey (NHANES) show that the prevalence of obesity (body mass index [BMI] 30 kg/m^2) continues to increase at about 2% per year, up to 33% of the adult population in the 2003–2004 survey. Particularly alarming is the rapidly increasing incidence of obesity in adolescents in the United States, such that for children aged 12–19 years, prevalence of obesity increased from 5% (in 1976–1980) to 17%. Increasing physical activity is an important goal to help combat obesity and its consequences. Although the AHA continues to promote a diet based largely on low saturated fat, more information is needed on the health consequences of all diets, especially given the lack of protection from a low-fat diet in the largest randomized study ever done, the Women's Health Initiative trial. Low carbohydrate diets, even when high in saturated fat, may improve the cholesterol profile in overweight men and are as effective at achieving weight loss. Fish, rich in omega-3 fatty acids, may help protect against vascular disease, and it is recommended that it be eaten three times a week by patients at risk.

Markers of inflammation are strong risk factors for CAD. High sensitivity (hs) CRP is the best-characterized inflammatory marker, but others include interleukin-6, CD-40 ligand, myelopyroxidase, and placental growth factor. Although CRP levels > 10 mcg/mL are often found in systemic inflammation, levels < 1, 1–3, and > 3 mcg/mL, respectively, identify patients at low, intermediate, and high risk for future cardiovascular events. The prognostic value of CRP levels is independent and additive to lipid levels. Use of CRP may be helpful in determining which patients at intermediate risk according to the Framingham 10-year risk of coronary heart disease calculation (score of 10–20%) are at high enough risk to warrant more intensive primary prevention, including use of statins to lower LDL cholesterol. HsCRP 2 mg/L identifies older people without vascular disease and with normal cholesterol who benefit from statins. CRP levels are often elevated in patients who have other conditions associated with accelerated atherosclerosis, such as diabetes, the metabolic syndrome, and obesity. In patients presenting with acute coronary syndromes, the CRP elevation identifies a group that is at high risk for early recurrent events.

Pathophysiology

The pathophysiology of atherosclerosis is well characterized. Abnormal lipid metabolism or excessive intake of cholesterol and saturated fats—especially when superimposed on a genetic predisposition—is important in early stages of the atherosclerotic process (see illustration). The initial step is the "fatty streak," or subendothelial accumulation of lipids and lipid-laden monocytes (macrophages) (see illustration). LDLs, especially small dense LDLs, are the major atherogenic lipid. HDLs, in contrast, are protective by virtue of their role in reverse cholesterol transport, removing cholesterol from the vascular wall. The pathogenetic role of other lipids, including triglycerides, is less clear. LDLs undergo in situ oxidation, which makes them more difficult to mobilize as well as locally cytotoxic.

Fig.

Lipid metabolism in relation to formation of atherosclerotic lesions. Fatty acids from dietary lipids are reesterified in intestinal cells and exported as protein-containing chylomicrons. Lipoprotein lipase from endothelial cells catalyzes the release of triglycerides from the chylomicrons, and the chylomicron remnants are taken up by the liver. In the liver, they take up cholesterol and are released into the bloodstream as very low density lipoprotein (VLDL) particles. These engage in exchange reactions with intermediate-density lipoproteins (IDL) and high-density lipoproteins (HDL). Low-density lipoprotein (LDL) particles are formed, and these constitute the major source of cholesterol for the tissues. Oxidized LDL enter the macrophages and smooth muscle cells, forming foam cells. In addition, HDL carry cholesterol from tissues to the liver for excretion in the bile, and LDL receptors in the liver (not shown) take up VLDL, IDL, and LDL, lowering circulating cholesterol. (Reproduced, with permission, from Hajjar DP, Nicholson AC: Atherosclerosis. Am Scientist 1995;83:460.)

Fig.
Formation of a fatty streak in an artery. Following vascular injury, monocytes bind to the endothelium, then cross it to the subendothelial space and become activated tissue microphages. The macrophages take up oxidized LDL, becoming foam cells. T cells release cytokines, which also activate macrophages. In addition, the cytokines cause smooth muscle cells to proliferate. Under the influence of growth factors, the smooth muscle cells then move to the subendothelial space, where they produce collagen and take up LDL, adding to the population of foam cells. (Reproduced, with permission, from Hajjar DP, Nicholson AC: Atherosclerosis. Am Scientist 1995;83:460.)

Macrophages migrate into the subendothelial space and take up lipids, giving them the appearance of "foam" cells. As the plaque progresses, smooth muscle cells also migrate into the lesion (see illustration). At this stage, the lesion may be hemodynamically insignificant, but endothelial function is abnormal and its ability to limit the entry of lipoproteins into the vessel wall is impaired. If the plaque remains stable, a fibrous cap forms, the lesion becomes calcified, remodeling of the vessel wall occurs, and ultimately the vessel lumen may become narrowed, although extensive atherosclerosis may be present even before this occurs.

Fig.

Mechanisms of production of atheroma. ***A:*** Structure of normal muscular artery. The adventitia, or outermost layer of the artery, consists principally of recognizable fibroblasts intermixed with smooth muscle cells loosely arranged between bundles of collagen and surrounded by proteoglycans. It is usually separated from the media by a discontinuous sheet of elastic tissue, the external elastic lamina. ***B:*** Platelet aggregates, or microthrombi, which may form as a result of adherence of the platelets to the exposed subendothelial connective tissue. Platelets that adhere to the connective tissue release granules whose constituents may gain entry into the arterial wall. Platelet factors thus interact with plasma constituents in the artery wall and may stimulate events shown in the next illustration. ***C:*** Smooth muscle cells migrating from the media into the intima through fenestrae in the internal elastic lamina and actively multiplying within the intima. Endothelial cells regenerate in an attempt to recover the exposed intima, which thickens rapidly, owing to smooth muscle proliferation and formation of new connective tissue. (Reproduced, with permission, from Ross R, Glomset JA: The pathogenesis of atherosclerosis. [Part 1.] N Engl J Med 1976;295:369.)

Atherosclerotic plaques may remain stable or progress only gradually, and these may result in chronic stable angina, when myocardial oxygen demand may be greater than the limited flow past stenotic coronary artery segments. Precipitants include exercise, eating, cold weather, and emotional stress. Some episodes of myocardial ischemia are symptomatic, causing angina pectoris; others are completely silent.

Other plaques may rupture, often related to the inflammatory process and metalloproteinase activity. The rupture causes turbulent flow, extrusion of lipids and fatty gruel, and exposure of tissue factor that result in a cascade of events culminating in intravascular thrombosis. This may be accompanied by coronary vasospasm. The outcome of these events is determined in large part by whether the vessel becomes occluded, which depends on the lesion anatomy as well as the balance of pro- and antithrombotic and pro- and antifibrinolytic forces. The result may be partial or complete vessel occlusion (causing acute coronary syndrome in the form of unstable angina (accelerating or new symptoms of myocardial ischemia at rest or minimal activity) or myocardial infarction), or the plaque may become restabilized, often with more severe stenosis. There is a predilection for these episodes to occur in the early morning or shortly after arising. Transient occlusion and/or embolization of platelet and thrombin debris, which may result in elevation in serum troponin, predispose to clinical events and portend a worse prognosis.

Several features are associated with enhanced plaque vulnerability, including a higher lipid content, a higher concentration of macrophages, especially in the plaque shoulder, and a very thin fibrous cap. Lesions with these characteristics are often relatively early lesions that can be responsible for acute myocardial infarction or sudden death as the first manifestation of coronary disease. This abrupt progression explains why most infarctions do not occur at the site of preexisting critical stenosis. Conversely, the relatively greater reduction in clinical events than in lesion severity in lipid-lowering treatment trials is probably explained by the stabilization of these early nonfibrotic lesions.

Myocardial Hibernation & Stunning

Areas of myocardium that are persistently underperfused but still viable may develop sustained contractile dysfunction. This phenomenon, which is termed "myocardial hibernation," appears to represent an adaptive response that maybe associated with depressed LV function. It is important to recognize this phenomenon, since this form of dysfunction is reversible following coronary revascularization. Hibernating myocardium can be identified by radionuclide testing, positron emission tomography (PET), contrast-enhanced MRI, or its retained response to inotropic stimulation with dobutamine. A related phenomenon, termed "myocardial stunning," is the occurrence of persistent contractile dysfunction following prolonged or repetitive episodes of myocardial ischemia. Clinically, myocardial stunning is often seen after reperfusion of acute myocardial infarction.

Primary & Secondary Prevention of Coronary Heart Disease

Although many risk factors for CAD are not modifiable, it is now clear that interventions such as smoking cessation, treatment of dyslipidemia, and lowering of BP can both prevent coronary disease and delay its progression and complications after it is manifest. Treatment of lipid abnormalities delays the progression of atherosclerosis and in some cases may produce regression. Even in the absence of regression, fewer new lesions develop, endothelial function may be restored, and coronary event rates are markedly reduced in patients with clinical evidence of vascular disease.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

A series of clinical trials has demonstrated the efficacy of hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) in preventing death, coronary events, and strokes. Beneficial results have been found in patients who have already experienced coronary events (secondary prevention), in those at particularly high risk for events (diabetics and patients with peripheral artery disease), and those with elevated LDL cholesterol without multiple risk factors, and those without vascular disease or diabetes with elevated hsCRP with normal LDL levels. Benefits occurred regardless of age, race, or the presence of hypertension. Treatment with statins can prevent coronary events and stroke in patients without clinically manifest atherosclerosis (primary prevention) and LDL levels as low as 130 mg/dL, or even lower if in presence of elevated hsCRP. It is also clear that for patients with vascular disease, statins provide benefit for those with normal cholesterol levels, and that more aggressive statin use is associated with greater benefits. The Heart Protection Study demonstrated that simvastatin 40 mg a day reduces vascular events by more than 20% in patients with prior myocardial infarction, stroke, peripheral vascular disease, or diabetes with total cholesterol levels as low as 135 mg/dL. The treatment benefit was similar regardless of baseline LDL cholesterol, with equal benefit above or below 100 mg/dL. This result suggests that all patients at significant risk for vascular events should receive a statin regardless of their cholesterol levels. The PROVE-IT trial showed that vascular events were reduced with more aggressive lipid lowering (atorvastatin 80 mg/d compared to pravastatin 40 mg/d following an acute coronary syndrome), providing more evidence of "lower is better" for patients with vascular disease. The TNT (Treating to New Targets) trial likewise found greater benefit with more aggressive LDL lowering (atorvastatin 80 mg versus 10 mg) in a population of patients with coronary heart disease and LDL cholesterol < 130 mg/dL. The IDEAL (Incremental Decrease in End Points Through Aggressive Lipid Lowering) trial provided only modest support for very aggressive lipid lowering, showing a nonstatistically significant reduction in major coronary events with 80 mg/d of atorvastatin compared with 20 mg/d of simvastatin in patients with prior myocardial infarction. Although true regression of plaque is uncommon even with intensive lipid therapy (as in the REVERSAL and ASTEROID trials), progression can be prevented at least in the short run in many patients. The failure of ezetimide and simvastatin versus simvastatin alone to reduce the progression of carotid intimal medial thickening in the ENHANCE trial has raised questions about whether the method of lowering LDL cholesterol may be important, and whether the LDL lowering of ezetimide leads to reduction in vascular events awaits the results of clinical outcome trials. The JUPITER trial showed that for men 50 years and women 60 years old, with LDL < 130 mg/dL and without cardiovascular disease or diabetes, and with hsCRP 2 mg/L, rosuvastatin 20 mg/d reduced cardiovascular events by 44%.

Treatment of abnormally low HDL levels or elevations of lipoprotein(a) and small, dense LDL particles is more difficult, but oral niacin in high dosages (2–3 g/d or more) may be effective. A trial in postinfarction patients has demonstrated that an increase in HDL levels with gemfibrozil (600 mg twice daily) in patients with relatively low LDL levels prolongs reinfarction-free survival, although the larger FIELD trial failed to show prevention of nonfatal myocardial infarction or coronary heart disease death with fenofibrate for patients with type 2 diabetes mellitus. The value of reducing elevated triglyceride levels is less clear, but since elevated triglycerides are often associated with other lipid abnormalities, treatment of high-risk patients with niacin, gemfibrozil, or fenofibrate for levels above 400 mg/dL is appropriate.

While antioxidant therapy has theoretical appeal, many large, well-controlled studies have failed to demonstrate a benefit with vitamin E therapy. In fact, the Heart Protection Study and the Heart Outcomes Prevention Evaluation (HOPE) trial found that vitamin E may even be harmful by increasing the likelihood of heart failure and other trials have suggested that vitamin E may hinder the effectiveness of statin therapy.

Elevated plasma homocysteine levels are associated with an increased risk of vascular events. Although homocysteine levels can be reduced with dietary supplements of folic acid (1 mg/d) in combination with vitamin B6 and vitamin B12 , two randomized clinical trials have shown that they are of little or no value in preventing vascular events.

Antiplatelet therapy is another very effective preventive measure. Aspirin (325 mg every other day) in males over the age of 50 years reduces the incidence of myocardial infarction. A similar approach (100 mg every other day), however, did not prevent myocardial infarction in women age 45 years or older, although stroke did appear to be reduced. Thus, the role of aspirin in primary prevention, including the dose, remains controversial. A prudent approach would be to administer 81–325 mg daily to men with multiple coronary risk factors or concomitant diabetes starting at age 45–50 years if no contraindication is present. While clopidogrel was found to be effective at preventing vascular events for 9–12 months after acute coronary syndromes, it was not found to be effective at preventing vascular events in the CHARISMA trial. This large trial included patients with clinically evident stable atherothrombosis or with multiple risk factors; all were treated with aspirin and observed for a median of 28 months. There may have been benefit for the group of patients with established vascular disease.

The previously mentioned GISSI Prevention Trial found a significant reduction in mortality with administration of omega-3 fatty acid (850 mg daily)—which has an antiplatelet effect in addition to other purported mechanisms—in postinfarction patients.

The effect of hormone replacement therapy in postmenopausal women has been clarified, and it is clear that neither combined estrogen–progesterone nor estrogen alone therapy is protective. In fact, both cause harm, although hormone replacement therapy for short-term management of menopausal symptoms appears to be relatively safe. Transdermal estrogen may have lower risk of thromboembolic disease than oral hormone replacement therapy. Control of BP has been shown to prevent infarctions. Individuals who exercise for at least 30 minutes a week are at lower risk for subsequent coronary events, and 30 minutes of exercise five times a week reduces the risk of developing diabetes in half among patients at risk.

The HOPE and the EUROPA trials demonstrated that ACE inhibitors (ramipril 10 mg/d and perindopril 8 mg/d, respectively) reduce fatal and nonfatal vascular events (cardiovascular deaths, nonfatal myocardial infarctions, and nonfatal strokes) by 20–25% in patients at high risk, including diabetics with additional risk factors or patients with clinical coronary, cerebral, or peripheral arterial atherosclerotic disease. The PEACE trial did not show benefit of the ACE inhibitor trandolapril in a lower-risk population of patients with coronary heart disease, most of whom had been treated aggressively with medical and revascularization therapies. An overview of these trials has demonstrated that while low-risk patients may not derive substantial benefits from ACE inhibitors, most patients with vascular disease, even in the absence of heart failure or LV dysfunction, should be treated with an ACE inhibitor.

Angiotensin receptor blockers may have similar effects as ACE inhibitors in preventing vascular events, as shown in the 25,620 patient ONTARGET trial that randomized patients to ramipril, telmisartan, or both. Outcomes were similar with ramipril and telmisartan, and there was no added benefit (and increased risk of kidney dysfunction and hypotension) with using both. However, the use of telmisartan in patients intolerant to ACE inhibitors did not show a significant benefit in reducing cardiovascular death, myocardial infarction, stroke, or heart failure hospitalization in the TRANSCEND trial.

Chronic Stable Angina Pectoris

Essentials of Diagnosis

- Precordial chest pain, usually precipitated by stress or exertion, relieved rapidly by rest or nitrates.
- ECG or scintigraphic evidence of ischemia during pain or stress testing.
- Angiographic demonstration of significant obstruction of major coronary vessels.

General Considerations

Angina pectoris is usually due to atherosclerotic heart disease. Coronary vasospasm may occur at the site of a lesion or, less frequently, in apparently normal vessels. Other unusual causes of coronary artery obstruction such as congenital anomalies, emboli, arteritis, or dissection may cause ischemia or infarction. Angina may also occur in the absence of coronary artery obstruction as a result of severe myocardial hypertrophy, severe aortic stenosis or regurgitation, or in response to increased metabolic demands, as in hyperthyroidism, marked anemia, or paroxysmal tachycardias with rapid ventricular rates. Rarely, angina occurs with angiographically normal coronary arteries and without other identifiable causes. This presentation has been labeled **syndrome X** and is most likely due to inadequate flow reserve in the resistance vessels (microvasculature). Syndrome X remains difficult to diagnose. Although treatment is often not very successful in relieving symptoms, the prognosis of syndrome X is good.

Clinical Findings

Symptoms

The diagnosis of angina pectoris depends principally upon the history, which should specifically include the following information: circumstances that precipitate and relieve angina, characteristics of the discomfort, location and radiation, duration of attacks, and effect of nitroglycerin.

Circumstances that precipitate and relieve angina

Angina occurs most commonly during activity and is relieved by resting. Patients may prefer to remain upright rather than lie down, as increased preload in recumbency increases myocardial work. The amount of activity required to produce angina may be relatively consistent under comparable physical and emotional circumstances or may vary from day to day. The threshold for angina is usually less after meals, during excitement, or on exposure to cold. It is often lower in the morning or after strong emotion; the latter can provoke attacks in the absence of exertion. In addition, discomfort may occur during sexual activity, at rest, or at night as a result of coronary spasm.

Characteristics of the discomfort

Patients often do not refer to angina as "pain" but as a sensation of tightness, squeezing, burning, pressing, choking, aching, bursting, "gas," indigestion, or an ill-characterized discomfort. It is often characterized by clenching a fist over the mid chest. The distress of angina is rarely sharply localized and is not spasmodic.

Location and radiation

The distribution of the distress may vary widely in different patients but is usually the same for each patient unless unstable angina or myocardial infarction supervenes. In most cases, the discomfort is felt behind or slightly to the left of the mid sternum. When it begins farther to the left or, uncommonly, on the right, it characteristically moves centrally substernally. Although angina may radiate to any dermatome from C8 to T4, it radiates most often to the left shoulder and upper arm, frequently moving down the inner volar aspect of the arm to the elbow, forearm, wrist, or fourth and fifth fingers. It may also radiate to the right shoulder or arm, the lower jaw, the neck, or even the back.

Duration of attacks

Angina is generally of short duration and subsides completely without residual discomfort. If the attack is precipitated by exertion and the patient promptly stops to rest, it usually lasts less than 3 minutes. Attacks following a heavy meal or brought on by anger often last 15–20 minutes. Attacks lasting more than 30 minutes are unusual and suggest the development of unstable angina, myocardial infarction, or an alternative diagnosis.

Effect of nitroglycerin

The diagnosis of angina pectoris is strongly supported if sublingual nitroglycerin promptly and invariably shortens an attack and if prophylactic nitrates permit greater exertion or prevent angina entirely.

Signs

Examination during angina frequently reveals a significant elevation in systolic and diastolic BP, although hypotension may also occur, and may reflect more severe ischemia or inferior ischemia (especially with bradycardia) due to a Bezold–Jarisch reflex. Occasionally, a gallop rhythm and an apical systolic murmur due to transient mitral regurgitation from papillary muscle dysfunction are present during pain only. Supraventricular or ventricular arrhythmias may be present, either as the precipitating factor or as a result of ischemia (see ECG); (see ECG).

It is important to detect signs of diseases that may contribute to or accompany atherosclerotic heart disease, eg, diabetes mellitus (retinopathy or neuropathy), xanthelasma, tendinous xanthomas (see photograph), hypertension, thyrotoxicosis, myxedema, or peripheral vascular disease. Aortic stenosis or regurgitation, hypertrophic cardiomyopathy, and mitral valve prolapse should be sought, since they may produce angina or other forms of chest pain ; ; ; .

Audio

Hypertrophic obstructive cardiomyopathy (HOCM). A mid-systolic rough 3/6 murmur and S2 is heard with the patient supine. This murmur is louder when the patient stands, performs a Valsalva maneuver, or inhales amyl nitrite. (Reproduced, with permission, from T. Anthony Don Michael, MD: *Mastering Auscultation* [CD-ROM], 2000.)

Laboratory Findings

Other than standard laboratory tests to evaluate for acute coronary syndrome (troponin and CK-MB), factors contributing to ischemia (such as anemia), and to screen for risk factors that may increase the probability of true coronary heart disease (such as hyperlipidemia), blood tests are not helpful to diagnose chronic angina.

ECG

The resting ECG is often normal in patients with angina. In the remainder, abnormalities include old myocardial infarction, nonspecific ST–T changes, and changes of LVH (see ECG); (see ECG); (see ECG). During anginal episodes, as well as during asymptomatic ischemia, the characteristic ECG change is horizontal or downsloping ST-segment depression that reverses after the ischemia disappears (see ECG). T wave flattening or inversion may also occur. Less frequently, transient ST-segment elevation is observed; this finding suggests severe (transmural) ischemia from coronary occlusion, and it can occur with coronary spasm (see ECG).

Fig.

First-degree atrioventricular (AV) block. The PR interval is prolonged to 0.28 s. The laddergram beneath the ECG illustrates the three levels of AV conduction: the atrium, the AV node, and the ventricles, with the delay in AV conduction represented as occurring in the AV node. Exercise ECG

Exercise testing is the most commonly used noninvasive procedure for evaluating for inducible ischemia in the patient with angina. Exercise testing is often combined with imaging studies (nuclear, echocardiography, or MRI [see below]), but in patients without baseline ST segment abnormalities or in whom anatomic localization is not necessary, the exercise ECG remains the recommended initial procedure because of considerations of cost and convenience.

Exercise testing can be done on a motorized treadmill or with a bicycle ergometer. A variety of exercise protocols are utilized, the most common being the Bruce protocol, which increases the treadmill speed and elevation every 3 minutes until limited by symptoms. At least two ECG leads should be monitored continuously.

Precautions and risks

The risk of exercise testing is about one infarction or death per 1000 tests, but individuals who have pain at rest or minimal activity are at higher risk and should not be tested. Many of the traditional exclusions, such as recent myocardial infarction or CHF, are no longer used *if the patient is stable and ambulatory*, but symptomatic aortic stenosis remains a contraindication.

Indications

Exercise testing is used (1) to confirm the diagnosis of angina; (2) to determine the severity of limitation of activity due to angina; (3) to assess prognosis in patients with known coronary disease, including those recovering from myocardial infarction, by detecting groups at high or low risk; (4) to evaluate responses to therapy; and (5) less successfully, to screen asymptomatic populations for silent coronary disease. The latter application is controversial. Because false-positive tests often exceed true positives, leading to much patient anxiety and self-imposed or mandated disability, exercise testing of asymptomatic individuals should be done only for those at high risk, those whose occupations place them or others at special risk (eg, airline pilots), and older individuals commencing strenuous activity.

Interpretation

The usual ECG criterion for a positive test is 1 mm (0.1 mV) horizontal or downsloping ST-segment depression (beyond baseline) measured 80 milliseconds after the J point (see ECG). By this criterion, 60–80% of patients with anatomically significant coronary disease will have a positive test, but 10–30% of those without significant disease will also be positive. False-positives are uncommon when a 2-mm depression is present. Additional information is inferred from the time of onset and duration of the ECG changes, their magnitude and configuration, BP and heart rate changes, the duration of exercise, and the presence of associated symptoms. In general, patients exhibiting more severe ST-segment depression (> 2 mm) at low workloads (< 6 minutes on the Bruce protocol) or heart rates (< 70% of age-predicted maximum)—especially when the duration of exercise and rise in BP are limited or when hypotension occurs during the test—have more severe disease and a poorer prognosis. Depending on symptom status, age, and other factors, such patients should be referred for coronary arteriography and possible revascularization. On the other hand, less impressive positive tests in asymptomatic patients are often "false-positives." Therefore, exercise testing results that do not conform to the clinical picture should be confirmed by stress imaging.

Fig.
Abnormal exercise ECG in a patient with severe three-vessel coronary artery disease and chest pain. The resting ECG shows horizontal ST depression in leads II, aVF, and V_3, and downsloping ST depression in lead V_1. After exercise, downsloping ST depression is present in leads II, aVF, and V_{2-5}. The additional 1 or more mm of J point depression as well as the changes in ST-segment configuration constitute an ischemic response, despite the baseline ECG abnormalities. (Reproduced, with permission, from Goldschlager N, Goldman MJ: *Principles of Clinical Electrocardiography*, 13th ed. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Myocardial Stress Imaging

Myocardial stress imaging (scintigraphy, echocardiography, or MRI) is indicated (1) when the resting ECG makes an exercise ECG difficult to interpret (eg, left bundle branch block, baseline ST–T changes, low voltage); (2) for confirmation of the results of the exercise ECG when they are contrary to the clinical impression (eg, a positive test in an asymptomatic patient); (3) to localize the region of ischemia; (4) to distinguish ischemic from infarcted myocardium; (5) to assess the completeness of vascularization following bypass surgery or coronary angioplasty; or (6) as a prognostic indicator in patients with known coronary disease.

Myocardial perfusion scintigraphy

This test provides images in which radionuclide uptake is proportionate to blood flow at the time of injection. Thallium-201, technetium-99m sestamibi, and tetrafosmin are most frequently used. If the radiotracer is injected during exercise or dipyridamole- or adenosine-induced coronary vasodilation, scintigraphic defects indicate a zone of hypoperfusion that may represent either ischemia or scar. If the myocardium is viable, as relative blood flow equalizes over time or during a scintigram performed under resting conditions, these defects tend to "fill in" or reverse, indicating reversible ischemia (see ECG); (see ECG). Defects observed when the radiotracer is injected at rest or still present 3–4 hours after an injection during exercise or pharmacologic vasodilation (intravenous adenosine or dipyridamole) usually indicate myocardial infarction (old or recent) but may be present with severe ischemia. Occasionally, other conditions, including infiltrative diseases (sarcoidosis, amyloidosis), left bundle branch block, and dilated cardiomyopathy, may produce resting or persistent perfusion defects.

Fig.

Reversible inferior and lateral defects. A 64-year-old man with exertional chest pain. The angiogram showed 80% stenosis of the left circumflex coronary artery. Short ***(A)*** and vertical long ***(B)*** axis images show reversible inferior and lateral defects. (Courtesy of R Caretta, F Weiland, and M Ortiz.)

Fig.

Pre- and postoperative thallium-201 stress scintigrams and ECGs obtained before and after placement of right coronary (RCA) and left anterior descending (LAD) grafts for treatment of angina pectoris. The preoperative study revealed an inferior wall perfusion abnormality *(arrows)*. Perfusion is normal in the postoperative stress scintigram, and the patient was symptom-free. (ANT, anterior; LAO, left anterior oblique; LLAT, left lateral.) (Reproduced, with permission, from Greenberg BH et al: Thallium-201 myocardial perfusion scintigraphy to evaluate patients after coronary bypass surgery. Am J Cardiol 1978;42:167.)

Stress imaging is positive in about 75–90% of patients with anatomically significant coronary disease and in 20–30% of those without it. False-positive radionuclide tests may occur as a result of diaphragmatic attenuation or, in women, attenuation through breast tissue. Tomographic imaging (single-photon emission computed tomography, SPECT) can reduce the severity of artifacts. Gated imaging allows for analysis of ventricular size, EF, and regional wall motion (see scintigram); (see scintigram).

Fig.

Diastolic (D) and systolic (S) frames from an equilibrium multiple-gated blood pool scintigram in the right anterior oblique (RAO) and left anterior oblique (LAO) positions. The upper images were obtained on the second day after the patient suffered a myocardial infarction. Left ventricular function was better on this occasion than in the study illustrated below, obtained 3 weeks later when left ventricular failure had developed. (Reproduced, with permission, from Botvinick EH, Shames DM: *Nuclear Cardiology: Clinical Applications*. Williams & Wilkins, 1979.)

Fig.

Ischemic cardiomyopathy. Abnormal left ventricular function following coronary artery bypass surgery. ***A:*** The patient is a 68-year-old man with a prior myocardial infarction and recent coronary artery bypass surgery. Left anterior oblique view shows marked hypokinesis in the apex and septum. The left ventricle is dilated. The last frame is "noisy" because of occasional extrasystoles during acquisition. ***B:*** The summary report confirms the poor wall motion in the apex and septum. Global left ventricular ejection fraction was 27%. In patients with prior coronary artery bypass surgery, abnormalities in the septum ("paradoxical septal motion") are common and do not by themselves reliably reflect prior septal infarction. Note that there is compensation in the motion of the lateral wall with a regional ejection fraction of 60%. (Reproduced, with permission, from Baum S et al: *Atlas of Nuclear Medicine Imaging*, 2nd ed. Originally published by Appleton & Lange. Copyright © 1993 by The McGraw-Hill Companies, Inc.)

Radionuclide angiography

This procedure images the LV and measures its EF and wall motion. In coronary disease, resting abnormalities usually represent infarction, and those that occur only with exercise usually indicate stress-induced ischemia. Exercise radionuclide angiography has approximately the same sensitivity as thallium-201 scintigraphy, but it is less specific in older individuals and those with other forms of heart disease. The indications are similar to those for thallium-201 scintigraphy.

Stress echocardiography

Echocardiograms performed during supine exercise or immediately following upright exercise may demonstrate exercise-induced segmental wall motion abnormalities as an indicator of ischemia. This technique requires considerable expertise; however, in experienced laboratories, the test accuracy is comparable to that obtained with scintigraphy—though a higher proportion of tests is technically inadequate. While exercise is the preferred stress because of other information derived, pharmacologic stress with high-dose dobutamine (20–40 mcg/kg/min) can be used as an alternative to exercise (see Video). Echocardiography contrast agents allow for perfusion imaging and may improve the diagnostic accuracy of this form of testing, although these are not commonly used.

Other Imaging

Positron emission tomography

PET scanning uses positron-emitting agents to demonstrate either perfusion or metabolism of myocardium. PET scanning can accurately distinguish transiently dysfunctional ("stunned") myocardium from scar by showing persistent glycolytic metabolism with the tracer fluorodeoxyglucose (FDG) in regions with reduced blood flow. The newer SPECT camera can provide acceptable images without the more expensive PET technology.

CT and MRI scanning

CT scanning can image the heart and, with contrast medium and multislice technology, the coronary arteries, with increasing resolution. Excellent coronary artery images can be obtained by 64- and higher slice technology, and, if the images are normal, this technology has high specificity for excluding significant coronary artery disease.

Thus, this technology may be useful in evaluating patients with low likelihood of significant coronary artery disease who would otherwise have undergone coronary angiography. CT angiography may also be useful for evaluating chest pain and suspected acute coronary syndrome. However, the role of CT angiography in routine practice is yet to be established, since it currently requires a relatively large radiation exposure and contrast load.

Electron beam CT (EBCT) can quantify coronary artery calcification, which is highly correlated with atheromatous plaque and has high sensitivity, but low specificity, for obstructive coronary disease. Thus, although this test can stratify patients into lower and higher risk groups, the appropriate management of individual patients with asymptomatic coronary artery calcification—beyond aggressive risk factors modification—is unclear. According to the American Heart Association, persons who are at low risk (< 10% 10-year risk) or at high risk (> 20% 10-year risk) do not benefit from coronary calcium assessment (class III, level of evidence: B) (see Tables 28–2 and 28–3). However, in clinically selected, intermediate-risk patients, it may be reasonable to determine the atherosclerosis burden using EBCT in order to refine clinical risk prediction and to select patients for more aggressive target values for lipid-lowering therapies (class IIb, level of evidence: B).

Cardiac MRI provides high-resolution images of the heart and great vessels without radiation exposure or use of iodinated contrast media. It provides excellent assessment of pericardial disease, neoplastic disease of the heart, myocardial thickness, chamber size, and many congenital heart defects. It is an excellent noninvasive test for nonemergently evaluating dissection of the aorta. Rapid acquisition sequences is a useful alternative when the echocardiogram is suboptimal. Perfusion imaging can be done with gadolinium first pass perfusion using dobutamine or adenosine to produce pharmacologic stress. Advances have been made in imaging the proximal coronary arteries, but this application remains investigational.

Ambulatory ECG Monitoring

Ambulatory ECG recorders can monitor for ischemic ST-segment depression (see ECG). In patients with CAD, these episodes usually signify ischemia, even when asymptomatic ("silent"). In many patients, silent episodes are more frequent than symptomatic ones. In most cases, they occur in patients with other evidence of ischemia, so the role of ambulatory monitoring is limited.

Fig.

Holter monitor ECG of a 65-year-old man showing marked ST depression of myocardial ischemia when the patient carried out his ordinary work routine as a salesperson. There were no symptoms during the time of the ischemic changes on the ECGs, but angina pectoris of effort occurred at other times. (Courtesy of W Atchley.)

Coronary Angiography

Selective coronary arteriography is the definitive diagnostic procedure for CAD. It can be performed with low mortality (about 0.1%) and morbidity (1–5%), but the cost is high, and with currently available noninvasive techniques it is usually not indicated solely for diagnosis.

Coronary arteriography should be performed in the following circumstances if percutaneous transluminal coronary angioplasty or bypass surgery is a consideration:

1. Limiting stable angina despite an adequate medical regimen.
2. Clinical presentation (unstable angina, postinfarction angina, etc) or noninvasive testing suggests high-risk disease (see Indications for Revascularization).
3. Concomitant aortic valve disease and angina pectoris, to determine whether the angina is due to accompanying coronary disease.

4. Asymptomatic older patients undergoing valve surgery so that concomitant bypass may be done if the anatomy is propitious.
5. Recurrence of symptoms after coronary revascularization to determine whether bypass grafts or native vessels are occluded.
6. Cardiac failure where a surgically correctable lesion, such as LV aneurysm, mitral regurgitation, or reversible ischemic dysfunction, is suspected.
7. Survivors of sudden death or symptomatic or life-threatening arrhythmias when CAD may be a correctable cause.
8. Chest pain of uncertain cause or cardiomyopathy of unknown cause.

A narrowing greater than 50% of the luminal diameter is considered hemodynamically (and clinically) significant, although most lesions producing ischemia are associated with narrowing in excess of 70% (see Video); (see Video). In those with strongly positive exercise ECGs or scintigraphic studies, three-vessel or left main disease may be present in 75–95% depending on the criteria used. **Intravascular ultrasound** (IVUS) can be positioned within the artery and image beneath the endothelial surface. This technique is useful when the angiogram is equivocal as well as for assessing the results of angioplasty or stenting. In addition, IVUS is the invasive diagnostic method of choice for ostial left main lesions and coronary dissections.

LV Angiography

LV angiography is usually performed at the same time as coronary arteriography. Global and regional LV function are visualized, as well as mitral regurgitation if present. LV function is a major determinant of prognosis in coronary heart disease.

Differential Diagnosis

When atypical features are present—such as prolonged duration (hours or days) or darting, knifelike pains at the apex or over the precordium—ischemia is less likely.

Anterior chest wall syndrome is characterized by sharply localized tenderness of intercostal muscles. Inflammation of the chondrocostal junctions, which may be warm, swollen, and red, may result in diffuse chest pain that is also reproduced by local pressure (Tietze syndrome). Intercostal neuritis (due to herpes zoster, diabetes mellitus, for example) also mimics angina.

Cervical or thoracic spine disease involving the dorsal roots produces sudden sharp, severe chest pain suggesting angina in location and "radiation" but related to specific movements of the neck or spine, recumbency, and straining or lifting. Pain due to cervical or thoracic disk disease involves the outer or dorsal aspect of the arm and the thumb and index fingers rather than the ring and little fingers.

Reflux esophagitis, peptic ulcer, chronic cholecystitis, esophageal spasm, and functional gastrointestinal disease may produce pain suggestive of angina pectoris. The picture may be especially confusing because ischemic pain may also be associated with upper gastrointestinal symptoms, and esophageal motility disorders may be improved by nitrates and calcium channel blockers. Assessment of esophageal motility may be helpful.

Degenerative and inflammatory lesions of the left shoulder and thoracic outlet syndromes may cause chest pain due to nerve irritation or muscular compression; the symptoms are usually precipitated by movement of the arm and shoulder and are associated with paresthesias.

Pneumonia, pulmonary embolism, and spontaneous pneumothorax may cause chest pain as well as dyspnea. Dissection of the thoracic aorta can cause severe chest pain that is commonly felt in the back; it is sudden in onset, reaches maximum intensity immediately, and may be associated with changes in pulses. Other cardiac disorders such as mitral valve prolapse, hypertrophic cardiomyopathy, myocarditis, pericarditis, aortic valve disease, or RVH may cause atypical chest pain or even myocardial ischemia.

Treatment

Sublingual nitroglycerin is the drug of choice for acute management; it acts in about 1–2 minutes. Nitrates decrease arteriolar and venous tone, reduce preload and afterload, and lower the oxygen demand of the heart. As soon as the attack begins, one fresh tablet is placed under the tongue. This may be repeated at 3- to 5-minute intervals, but current recommendations are that if pain is not relieved or improving after 5 minutes, that the patient call 9-1-1. The dosage (0.3, 0.4, or 0.6 mg) and the number of tablets to be used before seeking further medical attention must be individualized. Nitroglycerin buccal spray is also available as a metered (0.4 mg) delivery system. It has the advantage of being more convenient for patients who have difficulty handling the pills and of being more stable. Nitroglycerin can also be used prophylactically before activities likely to precipitate angina. Pain not responding to three tablets or lasting more than 20 minutes may represent evolving infarction, and the patient should be instructed to seek immediate medical attention.

Prevention of Further Attacks

Aggravating Factors

Angina may be aggravated by hypertension, LV failure, arrhythmia (usually tachycardias), strenuous activity, cold temperatures, and emotional states. These factors should be identified and treated when possible.

Nitroglycerin

Nitroglycerin, 0.3–0.6 mg sublingually or 0.4–0.8 mg translingually by spray, should be taken 5 minutes before any activity likely to precipitate angina. Sublingual isosorbide dinitrate (2.5–10 mg) is only slightly longer-acting than sublingual nitroglycerin.

Long-acting nitrates

Longer-acting nitrate preparations include isosorbide dinitrate, 10–40 mg orally three times daily; isosorbide mononitrate, 10–40 mg orally twice daily or 60–120 mg once daily in a sustained-release preparation; oral

sustained-release nitroglycerin preparations, 6.25–12.5 mg two to four times daily; nitroglycerin ointment, 6.25–25 mg applied two to four times daily; and transdermal nitroglycerin patches that deliver nitroglycerin at a predetermined rate (usually 5–20 mg/24 h). The main limitation to long-term nitrate therapy is tolerance, which can be limited by using a regimen that includes a minimum 8- to 10-hour period per day without nitrates. Isosorbide dinitrate can be given three times daily, with the last dose after dinner, or longer-acting isosorbide mononitrate once daily. Transdermal nitrate preparations should be removed overnight in most patients.

Nitrate therapy is often limited by headache. Other side effects include nausea, light-headedness, and hypotension.

-Blockers

-Blockers are the only antianginal agents that have been demonstrated to prolong life in patients with coronary disease (post-myocardial infarction). They are at least as effective at relieving angina as alternative agents in studies employing exercise testing, ambulatory monitoring, and symptom assessment. -Blockers should be considered for first-line therapy in most patients with chronic angina.

-Blockers with intrinsic sympathomimetic activity, such as pindolol, are less desirable because they may exacerbate angina in some individuals and have not been effective in secondary prevention trials. The pharmacology and side effects of the -blockers are discussed in Chapter 11: Systemic Hypertension (Table 11–7). The dosages of all these drugs when given for angina are similar. The major contraindications are severe bronchospastic disease, bradyarrhythmias, and decompensated heart failure.

Calcium channel blocking agents

Unlike the -blockers, calcium channel blockers have not been shown to reduce mortality postinfarction and in some cases have increased ischemia and mortality rates. This appears to be the case with some dihydropyridines and with diltiazem and verapamil in patients with clinical heart failure or moderate to severe LV dysfunction. Meta-analyses have suggested that short-acting nifedipine in moderate to high doses causes an increase in mortality. It is uncertain whether these findings are relevant to longer-acting dihydropyridines. Nevertheless, considering the uncertainties and the lack of demonstrated favorable effect on outcomes, calcium channel blockers should be considered third-line anti-ischemic drugs in the postinfarction patient. Similarly, with the exception of amlodipine, which in the PRAISE trial proved safe in patients with heart failure, these agents should be avoided in patients with CHF or low EFs.

The pharmacologic effects and side effects of the calcium channel blockers are discussed in Chapter 11: Systemic Hypertension and summarized in Table 11–9. Diltiazem and verapamil are preferable as first-line agents because they produce less reflex tachycardia and because the former, at least, may cause fewer side effects. Nifedipine, nicardipine, and amlodipine are also approved agents for angina. Isradipine, felodipine, and nisoldipine are not approved for angina but probably are as effective as the other dihydropyridines.

Ranolazine

Ranolazine is the first new antianginal drug to be approved by the FDA in many years, and it is approved as first-line use for chronic angina. It decreases the late sodium current and thereby decreases intracellular calcium overload. Ranolazine has no effect on heart rate and blood pressure, and it has been shown in clinical trials to prolong exercise duration and time to angina, both as monotherapy and when administered with conventional antianginal therapy. It is safe to use with erectile dysfunction drugs. The usual dose is 500 mg orally twice a day. Because it can cause QT prolongation, it is contraindicated in patients with existing QT prolongation; in patients taking QT prolonging drugs, such as class I or III antiarrhythmics (eg, quinidine, dofetilide, sotalol); and in those taking potent and moderate CYP450 3A inhibitors. Of interest, in spite of the QT prolongation, there is a significantly lower rate of ventricular arrhythmias with its use following acute coronary syndromes, shown in the MERLIN trial. It also decreases occurrence of atrial fibrillation and results in a small decrease in Hgb$_{A1C}$. It is also contraindicated in patients with significant liver and kidney disease. Ranolazine is not to be used for treatment of acute anginal episodes.

Alternative and combination therapies

Patients who do not respond to one class of antianginal medication often respond to another. It may, therefore, be worthwhile to use an alternative agent before progressing to combinations. If the patient remains symptomatic, a -blocker and a long-acting nitrate or a -blocker and a calcium channel blocker (other than verapamil, where the risk of AV block or heart failure is higher) are the most appropriate combinations. A few patients will have a further response to a regimen including all three agents.

Platelet-inhibiting agents

Several studies have demonstrated the benefit of antiplatelet drugs for patients with stable and unstable vascular disease. Therefore, unless contraindicated, aspirin (81–325 mg daily) should be prescribed for all patients with angina. Clopidogrel, 75 mg daily, reduces vascular events in patients with stable vascular disease (as an alternative to aspirin) and in patients with acute coronary syndromes (in addition to aspirin). Thus, it is also a good alternative in aspirin-intolerant patients. Clopidogrel may rarely induce thrombotic thrombocytopenic purpura.

Risk reduction

Patients with coronary disease should undergo aggressive risk factor modification. This approach, with a particular focus on statin treatment, treating hypertension, stopping smoking, and exercise and weight control (especially for patients with metabolic syndrome or at risk for diabetes), may markedly improve outcome.

Revascularization

Indications

There is general agreement that otherwise healthy patients in the following groups should undergo revascularization: (1) Patients with unacceptable symptoms despite medical therapy to its tolerable limits. (2) Patients with left main coronary artery stenosis greater than 50% with or without symptoms. (3) Patients with three-vessel disease with LV dysfunction (EF < 50% or previous transmural infarction). (4) Patients with unstable angina who after symptom control by medical therapy continue to exhibit ischemia on exercise testing or monitoring. (5) Post-myocardial infarction patients with continuing angina or severe ischemia on noninvasive testing. The use of revascularization for patients with acute coronary syndromes and acute ST elevation myocardial infarction is discussed below.

In addition, many cardiologists have believed that patients with less severe symptoms should be revascularized if they have two-vessel disease associated with underlying LV dysfunction, anatomically critical lesions (> 90% proximal stenoses, especially of the proximal left anterior descending artery), or physiologic evidence of severe ischemia (early positive exercise tests, large exercise-induced thallium scintigraphic defects, or frequent episodes of ischemia on ambulatory monitoring). Two sources of data have tempered some of the enthusiasm for coronary intervention for stable angina. Drug-eluting stents, widely used because of their benefits in preventing restenosis, have been associated with higher rates of late stent thrombosis. In addition, data from the COURAGE trial have shown that for patients with chronic angina, percutaneous coronary intervention (PCI) offers no mortality benefit beyond excellent medical therapy, and relatively little long-term symptomatic improvement.

Type of procedure

Coronary artery bypass grafting

Coronary artery bypass grafting (CABG) can be accomplished with a very low mortality rate (1–3%) in otherwise healthy patients with preserved cardiac function. However, the mortality rate of this procedure rises to 4–8% in older individuals and in patients who have had a prior CABG.

Grafts using one or both internal mammary arteries (usually to the left anterior descending artery or its branches) provide the best long-term results in terms of patency and flow. Segments of the saphenous vein (or, less optimally, other veins) or the radial artery interposed between the aorta and the coronary arteries distal to the obstructions are also used. One to five distal anastomoses are commonly performed.

Minimally invasive surgical techniques utilize different approaches to the heart than standard sternotomy and cardiopulmonary bypass. The surgical approach may involve a limited sternotomy, lateral thoracotomy (MIDCAB), or thoracoscopy (port-access). These techniques allow earlier postoperative mobilization and discharge. They are more technically demanding, usually not suitable for more than two grafts, and do not have established durability. Bypass surgery can be performed both on circulatory support (on pump) and without direct circulatory support (off-pump). No evidence to date has demonstrated a clinical difference in outcomes with either technique.

The operative mortality rate is increased in patients with poor LV function (LV EF < 35%) or those requiring additional procedures (valve replacement or ventricular aneurysmectomy). Patients over 70 years of age, patients undergoing repeat procedures, or those with important noncardiac disease (especially chronic kidney disease and diabetes) or poor general health also have higher operative mortality and morbidity rates, and full recovery is slow. Thus, CABG should be reserved for more severely symptomatic patients in this group. Early (1–6 months) graft patency rates average 85–90% (higher for internal mammary grafts), and subsequent graft closure rates are about 4% annually. Early graft failure is common in vessels with poor distal flow, while late closure is more frequent in patients who continue smoking and those with untreated hyperlipidemia. Antiplatelet therapy with aspirin improves graft patency rates. Smoking cessation and vigorous treatment of blood lipid abnormalities (particularly with statins) are necessary. While the most important principle is to use proven doses of statins shown to improve outcomes in large trials, many advocate a goal for LDL cholesterol of 70–100 mg/dL and for HDL cholesterol of 45 mg/dL. Repeat revascularization (see below) may be necessitated because of recurrent symptoms due to progressive native vessel disease and graft occlusions. Reoperation is technically demanding and less often fully successful than the initial operation.

Percutaneous coronary intervention including stenting

PCI, including balloon angioplasty and coronary stenting, can effectively open stenotic coronary arteries (see Video); (see Video); (see Video). Coronary stenting, with either bare metal stents or drug-eluting stents, has substantially reduced restenosis. Stenting can also be used selectively for left main coronary stenosis, particularly when CABG is contraindicated.

Video
Coronary angiography of right coronary artery after

PTCA. (Courtesy of T Amidon and T Chou.)

PCI is possible but often less successful in bypass graft stenoses. Experienced operators are able to successfully dilate 90% of lesions attempted. The major early complication is intimal dissection with vessel occlusion, although this is rare with coronary stenting. The use of intravenous platelet glycoprotein IIb/IIIa inhibitors (abciximab, eptifibatide, tirofiban) has substantially reduced the rate of periprocedural myocardial infarction, and placement of intracoronary stents has markedly improved initial and long-term angiographic results, especially with complex and long lesions. After percutaneous coronary intervention, all patients should have CK-MB and troponin measured, and a new rise of greater than three times the upper limit of normal constitutes a significant periprocedural myocardial infarction. Acute thrombosis after stent placement can largely be prevented by aggressive antithrombotic therapy (long-term aspirin, 81–325 mg, plus clopidogrel, 300–600 mg loading dose followed by 75 mg daily, for between 30 days and 1 year, and with acute use of platelet glycoprotein IIb/IIIa inhibitors).

A major limitation with PCI has been **restenosis,** which occurs in the first 6 months in less than 10% of vessels treated with drug-eluting stents, 15–30% of vessels treated with bare metal stents, and 30–40% of vessels without stenting. Factors associated with higher restenosis rates include diabetes, small luminal diameter, longer and more complex lesions, and lesions at coronary ostia or in the left anterior descending coronary artery. Drug-eluting stents that elute antiproliferative agents such as sirolimus, everolimus, zotarolimus, or paclitaxel have substantially reduced restenosis (see Video); (see Video); (see Video). In-stent restenosis is often treated with either brachytherapy or restenting with drug-eluting stents, and rarely with brachytherapy. The nearly 2 million PCIs performed worldwide per year far exceeds the number of CABG operations, but the justification rationale for many of the procedures performed in patients with stable angina is unclear. The COURAGE trial has confirmed earlier studies in showing that even for patients with moderate anginal symptoms and positive stress tests, PCI provides no benefit over medical therapy with respect to death or with respect to death or myocardial infarction. PCI was more effective at relieving angina, although most patients in the medical group had improvement in symptoms. Thus, in patients with mild or moderate stable symptoms, aggressive lipid-lowering and antianginal therapy may be a preferable initial strategy, reserving PCI for patients with significant and refractory symptoms.

Several studies of PTCA, including with drug-eluting stents, versus CABG in patients with multivessel disease have been reported. The consistent finding has been comparable mortality and infarction rates over follow-up periods of 1–3 years but a high rate (approximately 40%) of repeat procedures following PTCA. Stroke rates are higher with CABG. As a result, the choice of revascularization procedure may depend on details of coronary anatomy and is often a matter of patient preference. However, it should be noted that less than 20% of patients with multivessel disease met the entry criteria for the clinical trials, so these results cannot be generalized to all multivessel disease patients. Outcomes with percutaneous revascularization in diabetics have generally been inferior to those with CABG. However, most of these trials preceded the widespread use of stenting.

Mechanical extracorporeal counterpulsation

Extracorporeal counterpulsation (ECP) entails repetitive inflation of a high-pressure chamber surrounding the lower half of the body during the diastolic phase of the cardiac cycle for daily 1-hour sessions over a period of 7 weeks. Randomized trials have shown that ECP reduces angina, improves exercise tolerance, and can reduce symptoms of heart failure.

Neuromodulation

Spinal cord stimulation can be used to relieve chronic refractory angina. Spinal cord stimulators are subcutaneously implantable via a minimally invasive procedure under local anesthesia.

Prognosis

The prognosis of angina pectoris has improved with development of therapies aimed at secondary prevention. Mortality rates vary depending on the number of vessels diseased, the severity of obstruction, the status of LV function, and the presence of complex arrhythmias (see illustration). Mortality rates are progressively higher in patients with one-, two-, and three-vessel disease and those with left main coronary artery obstruction (ranging from 1% per year to 25% per year). The outlook in individual patients is unpredictable, and nearly half of the deaths are sudden. Therefore, risk stratification is often attempted. Patients with accelerating symptoms have a poorer outlook. Among stable patients, those whose exercise tolerance is severely limited by ischemia (less than 6 minutes on the Bruce treadmill protocol) and those with extensive ischemia by exercise ECG or scintigraphy have more severe anatomic disease and a poorer prognosis. The Duke Treadmill Score, based on a standard Bruce protocol exercise treadmill test, provides an estimate of risk of death at 1 year. The score uses time on the treadmill, amount of ST-segment depression, and presence of angina (Table 10–4).

<table>
<tr><td colspan="3">Table 10–4. Duke treadmill score: Calculation and interpretation.</td></tr>
<tr><td colspan="2">Time in minutes on Bruce protocol =</td><td>______________</td></tr>
<tr><td colspan="2">–5 x amount of depression (in mm) =</td><td>______________</td></tr>

<tr><td>Total score</td><td>Risk Group</td><td>Annual</td></tr>
</table>

		Mortality
5	Low	0.25%
–10 to +4	Intermediate	1.25%
–11	High	5.25%

Trial Results

Several randomized trials have shown that over follow-up periods of several years, the mortality and infarction rates with percutaneous revascularization and CABG are generally comparable. Exceptions are patients with left main or three-vessel disease with reduced ventricular function, and perhaps diabetic patients, who have had better outcomes with CABG. The increasing popularity of PCI and stenting primarily reflects the lower cost and shorter hospitalization, the perception that CABG is best done only once and can be reserved for later, and the preference of patients for less invasive treatment. These arguments make PCI the procedure of choice for revascularization of single-vessel disease. The situation is less clear with multivessel disease. It should also be noted that the excellent outcome of patients treated medically has made it difficult to show an advantage with either revascularization approach except in patients who remain symptom limited or have left main lesions or three-vessel disease and LV dysfunction. The issue of late stent thrombosis is shifting the balance toward bare metal stents for many patients.

Coronary Vasospasm & Angina with Normal Coronary Arteriograms

Essentials of Diagnosis

- Precordial chest pain, often occurring at rest during stress or without known precipitant, relieved rapidly by nitrates.
- ECG evidence of ischemia during pain, sometime with ST-segment elevation, including by Holter monitor.
- Angiographic demonstration of no significant obstruction of major coronary vessels.
- Angiographic demonstration of coronary spasm that responds to intra-coronary nitroglycerin or calcium channel blockers.

General Considerations

Although most symptoms of myocardial ischemia result from fixed stenosis of the coronary arteries or intraplaque hemorrhage or thrombosis at the site of lesions, some ischemic events may be precipitated or exacerbated by coronary vasoconstriction.

Spasm of the large coronary arteries with resulting decreased coronary blood flow may occur spontaneously or may be induced by exposure to cold, emotional stress, or vasoconstricting medications, such as ergot derivative drugs. Spasm may occur both in normal and in stenosed coronary arteries. Even myocardial infarction may occur as a result of spasm in the absence of visible obstructive coronary heart disease, although most instances of such coronary spasm occur in the presence of coronary stenosis.

Cocaine can induce myocardial ischemia and infarction by causing coronary artery vasoconstriction or by increasing myocardial energy requirements. It also may contribute to accelerated atherosclerosis and thrombosis. The ischemia in **Prinzmetal (variant) angina** usually results from coronary vasoconstriction. It tends to involve the right coronary artery and there may be no fixed stenoses. Myocardial ischemia may also occur in patients with normal coronary arteries as a result of disease of the coronary microcirculation or abnormal vascular reactivity. This has been termed "syndrome X."

Clinical Findings

Ischemia may be silent or result in angina pectoris**.**

Prinzmetal (variant) angina is a clinical syndrome in which chest pain occurs without the usual precipitating factors and is associated with ST-segment elevation rather than depression. It often affects women under 50 years of age. It characteristically occurs in the early morning, awakening patients from sleep, and is apt to be associated with arrhythmias or conduction defects. It may be diagnosed by challenge with ergonovine (a vasoconstrictor), although the results of such provocation are not specific and it entails risk.

Treatment

Patients with chest pain associated with ST-segment elevation should undergo coronary arteriography to determine whether fixed stenotic lesions are present. If they are, aggressive medical therapy or revascularization is indicated, since this may represent an unstable phase of the disease. If significant lesions are not seen and spasm is suspected, avoidance of precipitants such as cigarette smoking and cocaine is the top priority. Episodes of coronary spasm generally respond well to nitrates, and both nitrates and calcium channel blockers (including long-acting nifedipine, diltiazem, or amlopidine) are effective prophylactically. By allowing unopposed $_1$-mediated vasoconstriction, -blockers have exacerbated coronary vasospasm, but they may have a role in management of patients in whom spasm is associated with fixed stenoses.

Acute Coronary Syndromes without ST Segment Elevation

Essentials of Diagnosis

- Acute coronary syndromes are classified based on presenting ECG
    - Non–ST-segment elevation acute coronary syndrome
    - ST-segment elevation myocardial infarction
- Non–ST-segment elevation acute coronary syndrome is further divided into non–ST-elevation myocardial infarction or unstable angina, based primarily on presence or absence of elevation of cardiac biomarkers.
- CK-MB or troponin, or both, may be elevated or normal.

- ECG may show ST depression or T wave inversion, or may be normal.

General Considerations

Acute coronary syndromes comprise the spectrum of unstable cardiac ischemia from unstable angina to acute myocardial infarction. Acute coronary syndromes are classified based on the presenting ECG as either "ST segment elevation" (STEMI) or "non-ST segment elevation." This allows for immediate classification and guides determination of whether patients should be considered for acute reperfusion therapy. The evolution of cardiac biomarkers then allows determination of whether myocardial infarction has occurred. The universal definition of myocardial infarction in a rise of cardiac biomarkers with at least one value above the 99th percentile of the upper reference limit together with evidence of myocardial ischemia with at least one of the following: symptoms of ischemia, ECG changes of new ischemia, new Q waves, or imaging evidence of new loss of viable myocardium or new wall motion abnormality.

Acute coronary syndromes represent a dynamic state in which patients frequently shift from one category to another, as new ST elevation can develop after presentation and cardiac biomarkers can become abnormal with recurrent ischemic episodes.

Chest pain is one of the most frequent reasons for emergency department visits. Algorithms have been developed to aid in determining the likelihood that a patient has an acute coronary syndrome, and for those patients who do have an acute coronary syndrome, the risk of ischemic events and death.

Clinical Findings

Symptoms and Signs

Patients with acute coronary syndromes generally have symptoms and signs of myocardial ischemia either at rest or with minimal exertion. These symptoms and signs are similar to chronic angina symptoms described above, consisting of substernal chest pain or discomfort that may radiate to the jaw, left shoulder or arm. Dyspnea, nausea, diaphoresis or syncope may either accompany the chest discomfort or may be the only symptom of acute coronary syndrome. About one-third of patients with myocardial infarction have no chest pain per se—these patients tend to be older, female, have diabetes, and be at higher risk for subsequent mortality. Patients with acute coronary syndromes have signs of heart failure in about 10% of cases, and this is also associated with higher risk of death.

Many hospitals have developed **chest pain observation units** to provide a systematic approach toward serial risk stratification to improve the triage process. In many cases, those who have not experienced new chest pain and have insignificant ECG changes and no cardiac biomarker elevation undergo treadmill exercise tests or imaging procedures to exclude ischemia at the end of an 8- to 24-hour period and are discharged directly from the emergency department if these tests are negative.
